The incidence of the diagnosis of manic-depressive illness has varied considerably throughout the years. According to Cohen (1, p. 677), the incidence of the diagnosis has decreased over the past 50 years. He reported a decline of 17% to 8% in it at Boston State Hospital and a decline of 37% to 16% at McLean Hospital for the period 1900–1950. However, Cohen reported an increase in the diagnosis in general hospitals from 4,962 cases in 1951 to 6,335 in 1963.

Our general impression is that the incidence of the diagnosis is increasing. At our hospital the figures show that in 1954, no cases were recorded. However, there were 36 cases in 1964, 49 in 1974, and 57 by 1975. We believe there are several reasons why the incidence of the diagnosis is increasing.

Most authors describe three types of manic-depressive illness: manic, depressed, and cyclic. The manic patient, with pressure of speech, a disturbed sleep pattern, flight of ideas, and euphoric mood, poses little diagnostic problem. The patient who experiences severe mood swings from true mania to severe depression also poses little diagnostic difficulty. However, the patient who experiences recurrent depressions without any evidence of mania is much more of a diagnostic problem. We believe that most of these patients are increasingly diagnosed as having manic-depressive illness, depressed type, and that this fact accounts for the increased incidence of the diagnosis of manic-depressive illness. We suggest that diagnosing most recurrent depressive illness as manic-depressive illness is fraught with hazards; we believe that many of these disorders may be unrecognized anniversary reactions.

Anniversary reactions are time-specific psychological and, at times, physiological reactions that occur or recur at specific anniversaries in response to a trauma that the individual has experienced in the past and has not effectively mastered. The person attempts to master or control the trauma by reliving the experience—through symptom formation, dreams, or overt behavior—without necessarily being consciously aware that an anniversary reaction is occurring.

THE LITERATURE

The anniversary reaction was first described by Freud (2), who wrote in the case of Elizabeth von R., "This lady celebrated annual festivals of remembrance at the point of her various catastrophies, and on these occasions her vivid visual reproduction and expressions of feeling kept to the date precisely" (p. 163). Although Freud did not use the term "anniversary reaction," this is clearly what he described.

In 1920, in "Beyond the Pleasure Principle" (3), Freud attempted to explain masochism and other forms of pleasure that were not in keeping with the pleasure principle. He advanced the idea of the repetition compulsion; he felt that an individual made repeated attempts to master a traumatic situation that was so intense that it could not be mastered at the time it occurred. The clinical concept of the repetition compulsion is generally accepted today in psychiatry, and one of the more striking examples is the anniversary reaction.

Pollock (4), who has done extensive investigations on anniversary phenomena, has suggested that anniversary reactions result from incomplete or pathological mourning. He has described cases in which anniversary reactions were specific to a particular day of the week, hour of the day, or day of the year. His reported cases seem to validate his hypothesis of pathological mourning.

The authors are with the Veterans Administration Hospital, 508 Fulton St., Durham, N.C. 27705, where Dr. Cavenar is Chief, Psychiatry Service, Dr. Nash is Director, Mental Hygiene Clinic, and Dr. Maltbie is Director, Psychosomatic and Liaison Service, Psychiatry Service. They are also Associate Professors of Psychiatry, Duke University Medical Center, Durham, N.C.

Opinions expressed herein are those of the authors and do not necessarily reflect the views of the Veterans Administration.

Various diseases have been described as biological or somatic expressions of anniversary reactions. Bressler (5) has described the onset of ulcerative colitis as an anniversary response in which the loss of a significant external figure served to activate unconscious conflicts. Weiss and associates (6) have described hypertensive crises, occlusion of the coronary arteries, and irritable bowel syndromes as anniversary reactions. Other organic illnesses such as migraine headache (7), urticaria and dermatological conditions (8), and rheumatoid arthritis (9) have been described as anniversary reactions.

Hilgard has written extensively on anniversary phenomena and has described cases in which a parent experienced an anniversary reaction when his or her child reached the age at which the parent had experienced a trauma (10). She has also reported that depressive or psychotic symptoms may arise as anniversary reactions to the childhood death of siblings (11). In a third report (12) Hilgard presented material that described the appearance of an anniversary reaction when an adult patient reached the age at which a parent had died.

Engel (13), a psychiatrist and psychoanalyst, has recently written concerning his personal experiences with anniversary responses. He kept a detailed diary of his experiences and dreams and noted multiple examples of anniversary phenomena. These reactions were physical as well as psychological, and they seemed to be in reaction to the death of his identical twin, as well as to living through the age at which his father had died.

Cavenar and Nash (14) recently described patients with anniversary reactions who presented with physical complaints. The physical problems included psychogenic headache; back pain, depressive reaction; peptic ulcer; back pain, conversion reaction; and psychophysiological cardiac reaction. The dynamics in each case appeared to be an unresolved pathological grief reaction to a loss. The patients all responded to antidepressant medication and psychotherapy.

Cavenar and associates (15) also described a psychosis occurring in a young man when he reached the age at which his older sister had experienced an acute psychosis, and anniversary responses in two siblings after the father's death. These cases again seemed to be related to a pathological grief reaction.

The concept of anniversary phenomena was recently discussed in the lay press by Fishbien (16), who interviewed Pollock concerning his contributions to the field. In that report heart attacks, pleurisy and pneumonia, phobic fears, and successful suicides were identified as anniversary responses.

The purpose of this paper is to report several cases of cyclic depressive disorder, two of which were diagnosed by the referring physician as being manic-depressive illness, depressed type. It was only by careful interviewing and attention to temporal sequence that the underlying dynamics of anniversary reaction were ascertained. The following cases are illustrative.

CASE REPORTS

Case 1. The patient, a 24-year-old housewife and mother, sought psychiatric evaluation in April 1976 because of severe depressive symptoms. She was sleeping only about 2 hours per night, being awakened by marked anxiety, dreams, or nightmares. She had gained about 9.1 kg and felt she "had to eat everything in sight." She had frequent crying spells and felt as though life had no meaning for her. She had thought of committing suicide and had planned to do it by traffic accident so that it would appear to be accidental.

The mental status examination revealed a woman who was coherent, logical, and relevant and showed no evidence of psychosis or organic brain syndrome. She was profoundly depressed, had marked psychomotor retardation, and admitted to the symptoms noted above. She remarked that she had had similar episodes for the past 2 years, at the same time of the year, and had been told by a physician that she had manic-depressive illness, depressed type. She had been treated in the past with lithium carbonate, with a gradual resolution of the depression, and the lithium had been discontinued after the depression cleared.

The patient was finally able to date the onset of the symptoms of the current depressive episode to around Christmas 1975. Upon reflecting more, she realized that it was December 26, 1975, as well as December 26, 1974 and 1973, that had heralded the onset of the depressive symptoms. The depressive episode in 1973 had lasted for about 2 weeks and the one in 1974 for about 1 month; the current depressive episode was more intense both in severity and length.

The patient realized that her mother, with whom she had been very close, had entered a hospital on December 26, 1972, for a diagnostic evaluation. A diagnosis of carcinoma had been established, and the mother had survived until early June 1973. In spite of the fact that the mother lived another 6 months, it was "as though my relationship with her ended the day she entered the hospital." In many ways this date was more significant for the patient than the date on which the mother actually died.

The husband was interviewed, and he was even more emphatic than the patient about the significance of December 26. He talked of his wife retiring on Christmas night in good spirits, only to awaken the following morning profoundly depressed. He confirmed that this had occurred for 3 consecutive years and that this was the worst episode she had experienced.

It was recommended that the patient be hospitalized immediately, but she and her husband refused. She was started on therapeutic doses of amitriptyline and seen in insight-oriented psychotherapy. It became obvious during the brief psychotherapy that this woman had an unresolved grief reaction to a very significant loss and that her depressive episodes were on an anniversary basis. She obtained some insight into the unresolved grief, worked through many feelings, and clinically recovered from her depression.

Case 2. This patient, a 42-year-old married woman, was seen in psychiatric referral from her family physician. She complained of depressive symptoms, including crying spells, early morning awakening, anorexia with a 6.8 kg weight loss, and suicidal rumination. These symptoms had been present for 6 weeks prior to psychiatric evaluation and were gradually worsening. The referring physician had made a tentative diagnosis of manic-depressive illness, depressed type.

The mental status examination revealed a woman with profound depression. The affect was one of depression; she

cried readily and admitted to the symptoms noted above. She was not psychotic and had no organic impairment. The conversation revealed that she was preoccupied with the death of her son 5 years earlier.

The history revealed that the patient and her son, who was 12 years old at the time, were involved in an auto accident. She was only slightly injured, but her son was killed instantly. Her severe guilt over her son's death was apparent, and she related the onset of her depression and guilt to the fifth anniversary of the boy's death. She remarked that the other anniversaries did not seem to bother her and she was at a loss to explain why the fifth anniversary would do so.

During the course of the interview it was learned that when the patient was 5 years old, a younger male sibling had died suddenly of "summer diarrhea." She recalled that she had been very close to this brother but had not thought of him in years.

It seemed clear that the patient was suffering from an anniversary reaction based on unresolved grief over her son's death and also her brother's death many years earlier. Unconsciously she viewed the fifth anniversary of her own son's death as a double loss, corresponding to the age at which she had lost her own brother.

The patient was encouraged to ventilate her feelings over a period of 4 visits and was treated with appropriate levels of tricyclic antidepressants. She completely recovered from her depression in 1 month and returned to her usual level of functioning.

Case 3. This patient, a 60-year-old married man, was admitted to the urology service for prostatitis and sepsis. Psychiatric evaluation was requested because of his feelings of depression and crying spells. There was a history of similar episodes of depression with crying outbursts for each of the past 10 years, always between January and March. The patient's symptoms were more intense and severe this year than ever before. He could offer no explanation as to why he experienced the recurrent depressions in such a pattern.

The mental status examination revealed a man who had no symptoms of psychosis or organic impairment. He had a depressed affect and would burst into uncontrollable crying when he discussed reaching age 60 or the death of his mother, father, and brother. There was no sleep disturbance and he denied suicidal ideation.

The history revealed that the patient had been inducted into military service in early January 1942. At that time he was single and lived on a farm with his mother and father. He tried unsuccessfully to obtain deferment because his mother was critically ill. She died in March 1942, and the patient had had the fantasy since her death that if he had been allowed to remain at home, she would have suffered less or even survived. His father died 8 years later, in February. In addition, the patient's older brother had died at age 60 eight years earlier.

From the interview it became clear that the patient's recurrent depressions were an anniversary response. He had had multiple past traumata in January, February, and March, leading to unresolved grief reactions and recurrent depressions. The current depression was much worse than the others because he had now reached the age at which his brother had died; this, compounded by the previous trauma, deepened the severity.

Antidepressants were not required for the alleviation of the patient's depression; discussion of the genesis of the depression, plus sympathetic support, provided symptomatic relief. He was referred for outpatient psychotherapy in another city upon discharge from the hospital. It is hoped that additional insight into the dynamics of his depression, and an opportunity to grieve his losses in the psychotherapy, will prevent recurrences of the anniversary depressive reactions.

This patient could easily have been diagnosed as having manic-depressive illness, depressed type. The history of recurrent depressive episodes over a 10-year period, occurring at the same time of year, would tend to support that diagnosis. It was only through careful and complete interviewing that the true diagnosis became clear.

DISCUSSION

It was more than a theoretical and clinical exercise to establish the correct diagnosis and to understand the dynamics in these cases. The treatment of manic-depressive disorder with lithium carbonate for an extended period of time is not without hazard. Further, these patients would have benefited little, if at all, from lithium therapy, and it might have erroneously been assumed that they were treatment successes until the next anniversary reaction occurred. The implications of manic-depressive illness, from a social, professional, and financial standpoint, are quite different from the implications of an anniversary reaction.

In our experience the prognosis is good with anniversary depressive reactions if the correct diagnosis is established and proper treatment, consisting of antidepressant medication and insight-oriented psychotherapy, is instituted. We believe that many cases diagnosed as manic-depressive illness, depressed type, are actually anniversary reactions masquerading as manic-depressive illness.

Urinary Catecholamine Metabolites in Hyperkinetic Boys Treated with *d*-Amphetamine

BY WALID O. SHEKIM, M.D., HAROUTUNE DEKIRMENJIAN, PH.D., AND JAMES L. CHAPEL, M.D.

The authors studied the excretion of 3-methoxy-4-hydroxyphenyl glycol (MHPG), normetanephrine (NM), metanephrine, and homovanillic acid in 7 hyperactive and 12 control children. MHPG was lower but NM was significantly higher in hyperactive children than in controls. Administration of d*-amphetamine for 2 weeks depressed the levels of MHPG, NM, and metanephrine. The authors suggest a decreased central norepinephrine activity, which may be secondary to the interruption of norepinephrine fibers in the medial forebrain bundle.*

RECENT LITERATURE on the etiology of the hyperactive child syndrome (alternately called minimal brain dysfunction) suggests a variety of causes (1, 2), but it is generally agreed that a disorder in the catecholamine system, in the metabolism of either dopamine (DA) (3–7) or norepinephrine (NE) (8, 9) plays an important part in the causation. Since both of these catecholamines produce many of the same behavioral actions, there is some doubt as to which is really at fault.

A number of investigators suggest that 3-methoxy-4-hydroxyphenyl glycol (MHPG) is the main metabolite of central nervous system NE of various species, including man (10). It is also generally recognized that urinary MHPG derives, in part, from the central nervous system as well as from the sympathetic peripheral nervous system, but the percentage of MHPG that comes from the brain has not been determined; it is estimated that 30–50% of urinary MHPG comes from the metabolism of NE in the central nervous system of dogs and monkeys (11). In contrast, most if not all of urinary normetanephrine (NM) and metanephrine comes from the peripheral nervous system metabolism of NE and epinephrine, respectively (11, 12), while urinary homovanillic acid (HVA) derives from both central and peripheral metabolism of DA (13). It has been suggested that simultaneous assays of several of the catecholamine metabolites might allow one to make inferences as to the disposition of NE in central versus peripheral pools (14). *d*-Amphetamine, which has been shown to be clinically effective in controlling the hyperkinesis of about 70% of treated hyperactive children, has been shown to alter NE and DA metabolism (15).

This study attempts to present evidence that will support a relationship between central NE metabolism and hyperactivity and to demonstrate the effects of *d*-amphetamine on the central and peripheral metabolism of the catecholamines as reflected in the urinary metabolites studied (HVA, MHPG, NM, and metanephrine).

METHOD

We considered hyperactive boys, ages 7–12, of borderline intelligence or better and without gross neurological abnormalities for the study. If they met the cri-

teria for diagnosis of hyperkinetic reaction of childhood by *DSM-II* and by the children diagnostic classification and children diagnostic scale of the National Institute of Mental Health-Early Clinical Drug Evaluation Unit Program (NIMH-ECDEU) Assessment Battery for Pediatric Psychopharmacology, they were admitted to a research ward after having been free of all drugs for at least 2 weeks. (The first 3 children were studied in a preadolescent inpatient unit where W.S. is the clinical director.) Informed consent was obtained from all the children and their parents. All children were given a physical examination, the physical and neurological examination for soft signs, and an EEG. A complete psychological, educational, and behavioral evaluation was also made, the results of which will be given in a future report.

Twenty-four-hour urines on two successive days were obtained from 7 hyperactive children and 12 normal children (mean age=9.5±1.58 years and 10.5±1.25 years, respectively; p=n.s.) to measure HVA, MHPG, NM, and metanephrine. Diet control was not used in this pilot study, since its value in urinary catecholamine metabolites studies has recently been questioned (16, 17). Every effort was expended to make the urine collection as complete as possible (e.g., a Texas catheter was used on the one enuretic child). The biochemical assays were done by H.D., who had no knowledge of whether the urines were from normal children (controls) or hyperactive children (subjects). The methods employed for assay of metabolites have been described previously (11, 18). The subjects were discharged on *d*-amphetamine (0.5 mg/kg of body weight daily) and readmitted at the end of 2 weeks, and the metabolites were measured again. The controls, matched for age and sex, were compared with the subjects for metabolite excretion but were not given medication or placebo. Four 24-hour urine samples were collected from each normal and hyperactive child.

RESULTS

Values are expressed in micrograms per 24 hours and micrograms per milligrams of creatinine. Gitlow and coworkers (19) have shown that the excretion of catecholamine metabolites varies according to age, weight, and body surface; this variability can be decreased by expressing the results in micrograms of metabolite per milligram of urinary creatinine, which eliminates the problem of incomplete 24-hour urine collections. Mean creatinine values were 652±184 mg for controls and 560±147 mg for subjects; the subjects were physically smaller than the controls (mean weights were 27.5±5.4 kg and 31.04±6.66 kg, respectively). The differences in creatinine and weight means were statistically nonsignificant.

The differences in metabolite levels (expressed in micrograms per 24 hours) between subjects and controls were nonsignificant for HVA and metanephrine but were significant for MHPG and NM (table 1). Subjects excreted significantly lower levels of MHPG and significantly higher levels of NM than controls did. This finding is of some interest, since urinary NM is derived exclusively from the peripheral nervous system and is metabolized exclusively to MHPG. Increased metabolism of NE in the peripheral nervous system would lead to an increase in urinary NM and to an increase in the urinary MHPG coming from the metabolism of NE and NM in the periphery; therefore, a normal or low total urinary MHPG would indicate a decrease in the MHPG derived from the metabolism of NE in the central nervous system. The ratio of MHPG to NM may be considered an indication of central noradrenergic activity relative to its peripheral noradrenergic activity. The MHPG to NM ratio in our study was 6.9±1.7:1 for subjects and 11.4±3.2:1 for controls. The difference between the ratio was statistically significant. Others have used the MHPG to VMA (4-hydroxy-3-methoxymandelic acid) ratio similarly (20).

The administration of daily *d*-amphetamine significantly depressed the excretion of MHPG, NM, and M in hyperactive children compared with excretion of these metabolites in a drug-free state (table 1) and in controls. MHPG to NM ratio and HVA levels were not significantly changed by *d*-amphetamine.

DISCUSSION

Wender and associates (21) studied catecholamine metabolites in 9 children with minimal brain dysfunction and did not find significant differences between them and 4 control subjects. They also could not demonstrate any effect of *d*-amphetamine administration. Their study, however, did not describe the criteria for selection of the subjects; it included boys and girls, and amphetamine dosage and duration of treatment varied within the group. Shaywitz and associates (7) demonstrated a decrease in HVA accumulation in the CSF of 6 children with minimal brain dysfunction after probenecid ingestion, suggesting a decreased DA turnover in the central nervous system. Furthermore, they selectively reduced DA in rat brain by injecting 6-hydroxydopamine in an experimental animal model for minimal brain dysfunction and produced rat pups who were significantly more active than controls and who exhibited avoidance learning deficits (5).

Our finding of a low MHPG to NM ratio in subjects compared with controls suggests depressed central NE activity in the hyperactive child syndrome. The finding of significantly lower urinary MHPG levels in a group of depressed patients compared with controls while their urinary NM and metanephrine were the same as that of controls was interpreted by Maas and associates (22) as being consistent with and supportive of the catecholamine hypothesis of the affective disorders. This may also suggest cortical depletion of NE and subsequent depletion of its metabolite MHPG.

In animals, decreased urinary MHPG levels have

**There were only 6 hyperactive boys in this group because 1 boy developed tic-like movements, his hyperactivity worsened on *d*-amphetamine, and he was removed from the study before any data could be obtained for him while medicated.

been produced by the intraventricular administration of a neurotoxin that is believed to destroy catecholamine neuronal processes. For example, Breese and Traylor (23) found that an 82% depletion in rat brain NE stores following 6-hydroxydopamine administration resulted in a 29% decrease in total urinary MHPG. In nonhuman primates, Maas and associates (24) found that a 72% decrease in brain NE following 6-hydroxydopamine administration resulted in a 32% decrement in total urinary MHPG. Lesions to NE fibers in the medial forebrain bundle in animals have been shown to result in cortical depletion of NE and subsequent depletion of its metabolites (25).

Our findings and Shaywitz and associates' finding (5–7) of decreased DA levels and turnover in the brain may very well be related, since it has been suggested that NE may play a modulator role in the control of motor activity and its action may be facilitation of the nigro-neostriatal DA system of the brain (26). Andén and Grabowska (27) presented pharmacological evidence for a stimulation of DA neurons by NE neurons in the brain. Donaldson and associates (28, 29) presented evidence consistent with a proposed ceruleus-nigral NE pathway that enhances impulse flow in dopaminergic nigrostriatal system.

The reduction of MHPG levels by *d*-amphetamine in our study is in keeping with similar findings in some adult depressed patients demonstrated by Fawcett and associates (30) and Beckmann and associates (15). Amphetamine acts at the catecholamine-containing nerve terminals and results in an increase in the availability of neurotransmitter to postsynaptic receptors (31). Corrodi and associates (32) hypothesized that this increase in neurotransmitter level leads to an inhibition of catecholaminergic cell activity via neuronal feedback circuits. Bunney and Aghajanian (33, 34) presented evidence to support this hypothesis; from their data there is reason to believe that feedback control is present in the NE system and originates in the locus ceruleus, since amphetamine decreases activity in the locus (35). Bunney and Aghajanian (35) have submitted electrophysiological evidence supporting the view that central catecholaminergic neurons possess presynaptic receptors for their respective neurotransmitters and that these receptors are responsive to specific agonists and antagonists. Stimulation of presynaptic NE receptors through microionophoresis of NE or its agonist, clonidine, onto the soma of NE neurons inhibits the activity of these cells. Moreover, Walters and associates (36) demonstrated that both *d*- and *l*-amphetamine inhibit the firing of locus ceruleus neurons. Amphetamine may exert its action in hyperactive children through feedback inhibition of brain stem NE neurons.

In Vitro Half-Life of ^{14}C-Tryptamine in Whole Blood of Drug-Free Chronic Schizophrenic Patients

BY EDWARD F. DOMINO, M.D., AND SHEILA GAHAGAN

The authors found higher in vitro ^{14}C-tryptamine half-lives in the blood of 10 drug-free chronic schizophrenic patients than in the blood of 13 mentally normal control subjects. This finding was negatively correlated for both groups with platelet MAO activity. Repeated determinations of in vitro ^{14}C-tryptamine half-lives over a period of 5 months were positively correlated for the patients, although some blood samples showed statistically significant variability.

THE LITERATURE REGARDING platelet monoamine oxidase (MAO) activity in chronic schizophrenic patients is controversial. Many investigators have reported that platelet MAO activity is reduced in such patients (1–6), but others report normal values (7–10). At least four studies have shown that brain MAO activity in deceased chronic schizophrenic patients is normal (11–14), yet evidence that MAO inhibitors exacerbate psychotic behavior suggests that biogenic amines must be involved in such disorders (15). Of special interest is tryptamine, a substrate for both A and B type MAO (16) and a hallucinogen when given intravenously to human volunteers (17). One would predict that some drug-free chronic schizophrenic patients would have prolonged tryptamine blood half-lives both in vitro and in vivo. Inasmuch as an in vitro study was much simpler and would not have the potential to temporarily exacerbate the patient's illness, we decided to test this obvious hypothesis.

METHOD

We studied 10 drug-free chronic schizophrenic patients and 13 mentally normal adult men. Only patients and control subjects who signed informed consent forms were included. This study was approved by the Institutional Review Board of the Lafayette Clinic and the Technical Advisory Committee for Research of the Michigan Department of Mental Health.

All patients were diagnosed independently as chronic schizophrenics by three to five psychiatrists and were hospitalized in a special drug-free chronic schizophrenic ward at Lafayette Clinic. These patients had originally been selected for this ward because they failed to respond to antipsychotic drug therapy (dopamine antagonists). Most of the patients had been drug-free for approximately 10 years and had been mentally ill since adolescence or young adulthood. All patients exhibited thought disorder, disturbance of association, autistic behavior, and altered affect. The patients were between 30 and 46 years old and were on a diet of 2,300 calories and one vitamin pill (Myadec) a day. Recreational therapy included vigorous exercise each day.

The control subjects were 20- to 50-year-old men, chosen from Lafayette Clinic personnel. They had normal medical histories and psychiatric status. All controls were drug-free from 1 to 2 months before the test, excluding occasional use of acetylsalicylic acid, alcoholic beverages, and cigarettes. Acetylsalicylic acid and alcohol were not allowed for 24 hours before the test.

All patients and control subjects fasted overnight before blood withdrawal. Venous blood, 35 ml, was taken between 7:30 and 8:00 on the morning of the test. Heparinized whole blood was immediately transferred in 3-ml aliquots to 11 beakers in a Dubonoff shaker waterbath. The blood was incubated at 37°C in an atmosphere of 95% O_2 and 5% CO_2.

At the starting time 0.1 ml of 10^{-5} M ^{14}C-tryptamine was added to 10 of the 3-ml aliquots of blood. The total amount of tryptamine added to each sample was 1.1 μg containing .02 μCi or 44,000 disintegrations per minute of radioactivity. The 11th sample was a control to which no ^{14}C-tryptamine was added.

The blood samples were incubated for 0, 5, 30, 60, and 120 minutes. At each of these time intervals 5 ml of 10% trichloroacetic acid (TCA) was added to 2 of the blood samples to stop the reaction. The samples were then homogenized with the 10% TCA, and 4 ml 10% TCA was added in two successive washings. The total 12 ml of blood and TCA were basified with 2 ml of

10 N NaOH. The ^{14}C-tryptamine was extracted into a 50%-50% mixture of ethyl acetate and toluene and reconcentrated in 2 ml of 0.1 N HCl. This was again basified and extracted in ethyl acetate and toluene. At this point 2 ml of the final organic layer was mixed with 10 ml of Aquafluor and counted in a Beckman scintillation counter. Earlier, many of the patients and controls were studied for their platelet MAO activity using the same substrate, ^{14}C-tryptamine. The methods used have been described previously (5).

The data were analyzed on an IBM 1800 Process Control Computer. First the total disintegrations per minute counted were converted to nanograms of ^{14}C-tryptamine per milliliter of blood, which was then plotted against time. Half-life of ^{14}C-tryptamine in human blood was calculated using Gauss's nonlinear regression analysis.

RESULTS

The in vitro blood ^{14}C-tryptamine disappearance data for the 13 controls and 10 drug-free chronic schizophrenic patients are summarized in tables 1 and 2. The amount of ^{14}C-tryptamine in the blood of controls tended to decrease more rapidly. When each individual's data were used to determine in vitro half-life, the scattergram showed much greater variability among the patients than the controls (see figure 1). The mean half-life was significantly longer for patients than for controls—110.9±18.4 minutes versus 69.5±8.0 minutes, respectively ($p<.01$).

The mean platelet MAO activity for 9 patients was 3.34±.19 nmol/mg of protein per hour and 6.38±.83 nmol/mg of protein per hour for 8 controls. This difference, which was statistically significant ($p<.01$), has been reported previously (5). When platelet MAO activity of each subject was correlated with his whole blood ^{14}C-tryptamine half-life, the correlation coefficient was negative, as might be predicted ($r=-.45$; $p<.07$, two-tailed test; $p<.035$, one-tailed test).

Six of the 10 patients were retested 5 months later. Three showed very similar tryptamine half-lives on the first and second tests, but 3 varied markedly. The mean ^{14}C-tryptamine half-lives were 112.5±22.9 minutes and 181.3±37.2 minutes, respectively ($p<.02$). The two values for each subject correlated positively ($r=+.87$, $p<.03$).

DISCUSSION

The present findings stress again a biologic difference in the way the blood of chronic schizophrenic patients oxidizes a known hallucinogen, tryptamine, which is a trace endogenous brain amine (18). The fact that 3 of the 6 patients had widely different blood half-lives on test-retest conditions indicates that nongenetic factors must be very important. Wyatt and associates (2) have shown, using monozygotic twins divergent for schizophrenia, that platelet MAO activity was reduced in each twin. Although platelet MAO activity may be genetically predetermined, environmental factors must also be involved. The recent studies of Belmaker and colleagues (10) as well as Owen and associates (9) and others (7, 8), in which no difference in platelet MAO activity was found in chronic schizophrenic patients and normal controls, indicate that low platelet MAO activity cannot be regarded as a genetic marker for schizophrenia.

Inasmuch as whole blood contains a plasma amine oxidase as well as platelet MAO, in vitro studies of whole blood are relatively crude because one is measuring at least two different enzyme activities. Future studies of the activity of plasma amine oxidase should be compared to other monoamine oxidases such as those in the platelets of schizophrenic patients. However, the purpose of our study was to demonstrate an in vitro difference in tryptamine half-lives. Measurement of the presumed end product indoleacetaldehyde and its subsequently oxidized product indoleacetic acid would be a direct test for the involvement of oxidase enzymes. Disappearance of substrate is only indirect evidence that oxidases are involved since other products may be formed from tryptamine.

FIGURE 1
Scattergram of ^{14}C-Tryptamine Blood Half-Life In Vitro for Mentally Normal Controls and Drug-Free Chronic Schizophrenic Patients*

*The mean half-life was 110.9±18.4 minutes for patients and 69.5±8.0 minutes for controls ($p<.01$).

The half-life measurements we obtained in both normal subjects and chronic schizophrenic patients seemed to us surprisingly long. This would suggest our conditions for incubation were not ideal. Nevertheless, our study clearly indicates that further research, especially measuring in vivo tryptamine half-life in chronic schizophrenic patients and normal controls, is warranted. By using small intravenous doses of labeled tryptamine of high specific activity, one should be able to avoid hallucinogenic reactions (17) and do pharmacokinetic studies in schizophrenic patients. A tryptaminergic metabolic abnormality in some chronic schizophrenic patients resistant to antidopamine neuroleptic therapy still seems tenable.

The Hearst Trial and the Confidentiality of Residency Records

BY LENORE C. TERR, M.D.

Review of the Hearst trial transcript reveals that the subpoena of Dr. Joel Fort's residency files met with very little effective resistance on the part of the hospital that had trained him. There are few legal mechanisms to stop such a subpoena. The only truly effective solution may be the abstraction and destruction of residency files once the residency has been successfully completed.

NOW THAT THE Hearst trial is over, one question remains that must not escape the attention of all physicians: Why did Herrick Hospital give Dr. Joel Fort's residency files to F. Lee Bailey's team without a legal fight? Joel Fort, M.D., an expert witness for the government, had served his psychiatric residency at Herrick Memorial Hospital, Berkeley, Calif., in 1957 and 1958. In his cross-examination of Fort, Bailey produced some negative opinions about Fort's competence as a resident from his 18-year-old file. These opinions had been written by supervising psychiatrists on the hospital staff. The residency records were subpoenaed by the Hearst lawyers.

THE EXPERT WITNESS AND THE LAW OF EVIDENCE

An expert psychiatric witness must establish that he or she has skill, knowledge, and experience in the field of psychiatry. These qualifications must be demonstrated in direct testimony so that inferences and opinions made by the psychiatrist are admitted into evidence. Expert opinion and inferences are allowed by the courts in order to aid the judge and jurors with their understanding of the facts and to help them reach true and just conclusions.

On cross-examination of an expert, the attorney has the legal right to attempt to "elicit answers which will impeach the veracity, capacity to observe, impartiality, and consistency of the witness . . ." (1). Furthermore, the attorney has the right to ask questions that will impeach the witness' qualifications to aid the jury at all or make him appear to be less qualified than the psychiatric witnesses appearing for the cross-examining attorney.

Psychiatrists planning to appear in court are well-advised to read the chapters on cross-examination by Goulett (2) and Ziskin (3), both of whom are attorneys. Both authors explore in detail various methods of discrediting psychiatrists. Goulett, relying upon methods other than attacking the psychiatrist "within the heart of his field" (i.e., *why* he made the diagnosis), suggests impeaching the psychiatrist's credibility by asking about failed Board examinations, lack of forensic experience, too much forensic experience, or contradicting writings by eminent psychiatrists. Ziskin's cross-examination suggestions are aimed at discrediting the general field of psychiatry altogether. Although these authors recommend a thorough search for impeaching questions, neither suggests opening the residency file, as was done in the Hearst case. While this new tactic may be acceptable to the courts, it is most disturbing to training directors, department chairmen, and psychiatrists in general. In the future, it is very likely that many attorneys will use residency records in their armamentarium of cross-examination techniques.

THE CHAIN OF EVENTS

The following chain of events was reconstructed from the transcript of the Hearst trial.[1] On March 9, 1976, at about 9 a.m. the Fort file was subpoenaed, to be delivered to the court by about noon. Herrick Hospital's assistant administrator, Mr. Passama, appeared in court with two attorneys, Mr. Vlahos and Mr. Kessenick. In addition, a representative of Herrick Hospital phoned Mr. Davis, an attorney whose name had been mentioned in the newspapers in connection with some legal transactions of Dr. Fort's, to ask him to appear in court to represent Dr. Fort. Dr. Fort stated during cross-examination that he had not been notified by the hospital and did not know that an attorney would appear on his behalf (4, 3693:3–18). It is not usual and is not good court "etiquette" for an expert witness to be represented by counsel because it might detract from the main issues of the case.

At the time the records were delivered on March 9, the attorneys discussed the potential use of the residency files. The jury was not present. Dr. Fort's lawyer objected and attempted to quash the subpoena be-

Dr. Terr is Assistant Clinical Professor of Psychiatry, School of Medicine, University of California, San Francisco, and Lecturer, School of Law, University of California, Berkeley. Address reprint requests to Dr. Terr at 450 Sutter St., San Francisco, Calif. 94108.

[1]Citations are to the page and lines of the reporter's verbatim transcript of *U.S. v. Hearst* (4).

cause it was too broad, too remote in time, and was an abuse of confidence and privilege (4, 3483:11–25, 3484:1–25). In explaining what confidence was involved, Mr. Davis objected to the presence of another resident's name in Dr. Fort's file. The court and Bailey agreed that the other psychiatric trainee, Dr. "X," would not be mentioned by name. Judge Carter pointed out to Mr. Davis that there was no federal privilege extended to trainees, and there was no doctor-patient privilege in such circumstances. He denied the motion to quash the subpoena. The government attorney moved to quash the subpoena because Dr. Fort's file was a "side-issue, which has little to no bearing on the case whatsoever" (4, 3498:2–3). Judge Carter upheld the government's motion (4, 3501:14).

Unfortunately, there was a turn of events the next day, March 10. Mr. Browning, the government's attorney, in questioning Dr. Fort before the jury, asked him about his training. Mr. Bailey seized the opportunity to ask Judge Carter to rule again on the admission of Dr. Fort's residency file. This time Carter ruled that it could be admitted as evidence. There were no hospital attorneys or counsel for Dr. Fort present on March 10 when the residency file was used in open court in an attempt to discredit Dr. Fort's psychiatric opinion.

What was the role of the two attorneys for Herrick Hospital in the deliberations about using the residency files? They raised no serious objection. First Mr. Vlahos made the following policy statement: "We on behalf of the hospital were concerned only in that we felt any party who wanted to make his objections as to privacy and other privilege should make them" (4, 3487:8–10). Thus the hospital was allowing others to object but did not object itself to the use of its residency files. Mr. Vlahos asked that Dr. X not be mentioned, and all the attorneys agreed. Mr. Vlahos did not ask that a patient, Mrs. M., whose name and illness were disclosed in Dr. Fort's file, be protected. Finally the hospital attorney stated, "I would like to call to the Court's attention, without making any motion of any kind, a provision in California law which may or may not be applicable to these proceedings, Sections 1156 and 57 of the Evidence Code relating to medical staff records, and a privilege under California law with respect thereto" (4, 3490:2–8).[2] These rules relate primarily to medical malpractice suits. The minutes of peer review committees cannot be used in California to prove that a hospital was negligent. Thus the rules cited by the hospital did not apply. Furthermore, the hospital made "no motion of any kind" to protect highly sensitive material in its files.

On March 10, with full permission to use Dr. Fort's residency file, Bailey cross-examined Dr. Fort. Even though the judge and all of the participating attorneys had already read it the previous day, Dr. Fort had never seen his record before (4, 3693:19–25, 3694:1–19). Eleven staff psychiatrists whose statements were in Dr. Fort's record were named and discussed in the cross-examination. Mrs. M., a patient who had suffered a serious mental illness in 1958, was also named and discussed (4, 3688:11–12, 3689:13–16).

THE ISSUES

There are several issues involved in the use of residency records. First, there is the unique teacher-student relationship during residency, which is at least morally privileged if not legally privileged. Second, there is the issue of doctor-patient privilege, which applies when residency files contain patients' names and a discussion of their cases. Finally, there is the issue of the safekeeping of residency records.

The single most important factor necessitating the protection of psychiatric residency files is the quasi-patient relationship that exists between the resident and the senior staff. The resident often experiences this quasi-patient role when he or she tells the supervisor about personal problems as they relate to countertransference (5). In fact, at least one training program achieves a true doctor-patient relationship by encouraging the resident to use "an 'undirected, free-associational' technique" in supervisory hours (6), thus offering the trainee the "opportunity to use his supervisory time as therapy" (7). Returning to the more ordinary program, however, it is clear that when practicing psychiatrists work with psychiatrists-in-training, personal discussions, observations, and interpretations are made. These analyses often find their way into the psychiatrist resident's record at the training institution (8).

What are the results of exposing residency records in the courtroom? First, the lay jury will not automatically understand that supervisors' comments made during the formative residency years are meant as constructive criticism, not as a permanent blot on the psychiatrist's subsequent career. Second, because of the highly personal comments in residency files, most practicing psychiatrists will become more and more reluctant to testify. The risk of a full disclosure of material from training is serious enough to stop psychiatrists from serving as expert witnesses. Third, mental health professionals on the permanent staff of teaching hospitals may become less than candid in evaluating residents for fear of hearing their comments read in public at a later date. If this occurs, groups and institutions that rely on data from residency files (e.g., certification boards, medical organizations, hiring groups) will not receive the kind of useful information they now do. Finally, in an age of generational conflict, the disclosure of private and personal files can only add to the distrust of the young for the medical establishment.

The exposure of a patient's name was a tragic out-

[2]Section 1157 of the California Statute states, "Neither the proceedings nor the records of organized committees of medical or medical-dental staffs in hospitals having the responsibility of evaluation and improvement of the quality of care rendered in the hospital or medical and dental review committees of local medical or dental societies shall be subject to discovery."

come of the Bailey subpoena. No one protected the patient's right to confidentiality, a legally established privilege. One can only imagine the impact on Mrs. M. and her family when her mental illness of 1958 was brought up in the most highly publicized trial of the 1970s.

The third issue related to hospital records is the safekeeping of residency files. The immediate type of subpoena issued by Bailey caught the hospital unprepared. The officials of Herrick Hospital could have moved for a continuance (for a delay until their motions were prepared), but they did not. It is unlikely that Bailey would have subpoenaed this record without some clues. Bailey stated, as he attempted to offer proof to the court of the relevance of the records, "We have information he [Fort] was found not to be qualified to administer psychotherapy. . ." (4, 3488:14–15). Davis, Dr. Fort's attorney, replied, "from the information I have, that is an entirely false statement as to the fact and as to what is contained in these records. . ." (4, 3488:10–21). Bailey concluded, "I am sorry, Mr. Davis, we have talked with the administrator of the hospital. I think some of the documents I am talking about, you haven't seen" (4, 3489:1–3). All of these statements were made before the review of the residency files. From the colloquy, it is not unreasonable to infer that Bailey had been given sensitive information by a hospital administrator before the court discussion. Did Bailey actually see the record before its subpoena?

THE POSSIBLE SOLUTIONS

The use of residency files to discredit expert witnesses must be dealt with by psychiatry. Individual psychiatrists, training institutions, and organized psychiatry must be alert to the problem. The individual psychiatrist should inspect his own record if it is to be used in cross-examination. In examining it he can prepare himself for questions concerning supervisors' comments. The Buckley amendment (9, sections 438, 513) requires that the educational institution notify the student before it complies with a subpoena of its records. U.S. Department of Health, Education, and Welfare regulations for the enforcement of the Buckley amendment state that an educational institution must make "a reasonable effort to notify . . . the eligible student of the order of subpoena in advance of compliance therewith . . . (10, section 99.31 [a] [9]). Thus the Buckley amendment helps the expert witness in two ways—by allowing him to see his file in advance and by giving him prior notification that his file has been subpoenaed.

Training institutions have few, if any, effective legal grounds to quash subpoenas of their files even though they might wish to vigorously fight. However, legal delay tactics can be very effective. Particularly because the residency file is a side issue, the subpoenaing attorney may not pursue the matter if there is a legally obtained delay.

In the Hearst case, Federal Rules 611[3] and 403[4] might have been cited. Rule 611 protects the witness from harassment or undue embarrassment, and Rule 403 eliminates irrelevant evidence. State courts have similar rules (1). However, the courts tend to overrule attorneys' objections based on these rules when *expert* witnesses testify. The courts are not particularly protective of the expert, who the courts assume is appearing voluntarily and is being paid for his or her services. Furthermore, most judges would consider that information concerning residency training is relevant, regardless of how many years have passed, because the expert justifies his presence in court on the basis of his training and experience. Thus it is extremely difficult for a training institution to put up an effective fight.

At the psychiatric facility, training directors must handle residency files more carefully. Patients' names must be eliminated. Institutions must place residency files under lock and key and make them available to only a few authorized individuals.

Organized psychiatry needs to consider asking legislatures for an extension of privileges to cover trainee-institution relationships. The relationship between the psychiatric resident and the psychiatric supervisor is unique among medical specialty training relationships in that the trainee is "seeing a psychiatrist" when he or she visits his or her supervisor. It would be helpful to extend privilege to cover this relationship.

Finally, if such privilege rules are not forthcoming, psychiatric residency files must be destroyed once the residency has been completed. At present, it is extremely difficult to quash a subpoena of a residency file. Although files are useful for the first few years after graduation, they can be abstracted to include the subject matter covered, general quality of the resident's performance, and the dates the residency was begun and completed. If training institutions cannot effectively protect such records from use and misuse by investigating agencies and courts, then they must be destroyed.

To summarize, F. Lee Bailey's cross-examination of Dr. Joel Fort is a worrisome episode for all physicians, particularly psychiatrists. In the future, residency files must be zealously guarded by training institutions. If it is not possible to keep such records out of the courts, then it may be preferable to eliminate them altogether.

[3]Federal Rule 611 states, "The Judge shall exercise reasonable control over the mode and order of interrogating witnesses and presenting evidence so as (1) to make the interrogation and presentation effective for the ascertainment of the truth (2) to avoid needless consumption of time and (3) to protect witnesses from harassment or undue embarrassment."

[4]Federal Rule 403 states, "Although relevant, evidence may be excluded if its probative value is substantially outweighed by the danger of unfair prejudice, confusion of the issues, or misleading the jury or by considerations of undue delay, waste of time, or needless presentation of cumulative evidence."

Suicide Among Police

BY MICHAEL F. HEIMAN, M.D.

The author presents and comments on recently acquired police suicide data from several cities in the United States and from the Metropolitan Police Department of London and on extensive archival police suicide files. He also explores some of the psychosocial factors that may affect the high incidence of suicide among people who actively specialize in police work.

IN RECENT YEARS considerable interest has been shown in the phenomenon of suicide (1). Suicidal events have been observed in almost all cultural, religious, and political settings in spite of the diversity of attitudes and the variety of feelings enshrouding these settings (2, 3). One setting that is highly visible and intimately involved with such issues as death and violence but is not usually considered as harboring active participants in the process of termination by self-destruction is the police department. However, the standardized mortality ratio among law enforcement officials (police, sheriffs, and marshals) is one of the highest of any occupation studied by the U.S. Department of Health, Education, and Welfare (4)—183, compared with 100 for working men in all occupations (women were excluded from the study because at the time [1950] active police work was an almost exclusively male experience). Other studies have directly or indirectly come to a similar conclusion, i.e., American policemen kill themselves in proportionately greater numbers than do members of other public service occupations (5, 6).

Although Nelson and Smith (6) focused on the sociological aspects of police work from the theoretical perspective of Durkheim, most studies are primarily statistical in nature, providing little information as to the personal qualities and experiences of law officers who have committed suicide. Consequently, there appears to be a need for assessing suicide among police not only from sociometric and sociological perspectives (perhaps with a special focus on regional variation, the nature of the police institution, and the alternatives of Durkheim) but also from a psychological viewpoint, with more emphasis on the psychological autopsy and psychodynamic speculations of the single case study.

METHOD

Under the aegis of Dr. Edwin Shneidman, I obtained access to the original files and records of 93 New York City policemen who were alleged to have committed suicide between 1934 and 1940 (7). These files and records make up a small but exciting part of the Zilboorg-Friedman Archives in the Laboratory for the Study of Life Threatening Behavior at the University of California, Los Angeles. They were given to Dr. Shneidman by the estate of the late Dr. Paul Friedman. Dr. Friedman's description of the history of these archival ma-

Dr. Heiman is Chief, Medical/Dental Staff, Stockton Residential Facility, 510 E. Magnolia St., Stockton, Calif. 95202, and Clinical Instructor of Psychiatry, University of California, Davis, School of Medicine, Davis, Calif.

The author wishes to thank Dr. E. Shneidman for his inspiration and for the use of the Zilboorg-Friedman Archives at the University of California, Los Angeles. He also wishes to thank the chiefs of police and the police commissioners who cooperated with the collection of data and Ms. Jo Kennedy and the clerical staff of Stockton Residential Facility.

terials and his work with Dr. Zilboorg and the Committee for the Study of Suicide, Inc., has been published elsewhere (8).

The police files studied are pre-World War II equivalents of what has now become known as the psychological autopsy (9). They include not only the actual police department records but also extensive interviews with any significant friends, coworkers, and family members who could shed some light on the events immediately preceding the police officer's self-inflicted death.

A second part of the research involved corresponding with the chiefs of police or the police commissioners in approximately 30 major cities throughout the United States and with the Metropolitan Police Department of London. I did this to gain some idea of the incidence of police suicides since 1960 and to compare data from these cities with Friedman's data for New York City (7).

CASE REPORTS FROM THE ZILBOORG-FRIEDMAN FILE

Case 42.[1] This patrolman had been married twice, drank a lot, was educated through the eighth grade, was Catholic, and had one younger sibling. He joined the police force during the heyday of Jimmy Walker's mayoralty in New York City. His first marriage was turbulent; he and his wife were flagrantly unfaithful to each other. During one drunken episode, he shot himself in the leg after he and his first wife had a heated argument. He said of that incident, "I almost shot her at that time." About a year and a half before his suicide and eight months after his divorce he remarried. This marriage was also unrewarding, and his second wife's behavior may have contributed to his increased irritability.

At work he was one of the most surly, irascible patrolmen in the precinct. He felt his colleagues singled him out for being derelict in his duty and for being intoxicated while on patrol. He especially focused on a sergeant as the prime architect of the disciplinary actions taken against him.

On the day of his suicide, after a very trying day with this particular sergeant, the patrolman went to a local bar and waited for the sergeant to come there. He told some fellow drinkers that he would kill the sergeant when he saw him. He was agitated and frequently walked out of the bar looking for the sergeant. On his final return to the bar he wrote a note addressed to the sergeant: "To Whom It May Concern: Goodbye, you old prick, and when I mean prick you are a prick. Hope you fall with the rest of us, you yellow bastard." He shot himself in the head after finishing this note.

Case 43. This patrolman was a "good cop." He had been on the force for 12 years and, in spite of the rampant corruption of the department during the 1920s, had never taken a bribe. He was the eldest of five siblings and had been raised in a good Catholic household. He had taken on the sole responsibility of raising his younger siblings when his mother died during his teenage years. He had managed to go through one year of high school.

During the period near his death, he was suffering from uncontrolled diabetes and was probably going blind. He may have taken an overdose of insulin in a suicidal gesture just a few days before his actual death. At that time he was revived and told to return to work. The night before his death, he asked his wife if she knew another man to fall back on. During the day of his death, he seemed preoccupied with thoughts about dying. All of his debts had recently been paid up. He shot himself in the head, leaving a note indicating despondence over his uncontrolled diabetes.

[1]This case was also described by Friedman (7).

RECENT SUICIDE STATISTICS

Much of the descriptive and statistical data collected on New York City police during the heyday of Tammany Hall and in the early years of Fiorello La Guardia's mayoralty can be found in Friedman's work (7) and in the Zilboorg-Friedman Archives. More recent statistical data from the Metropolitan Police Department of London and from the New York City Police Department have been published elsewhere (10, 11). Unpublished data on the method of suicide, number of years on the police force, age, and marital status of the London police suicides since 1960 are shown in table 1.

It is clear from the London data that the typical police suicide for that city was married, in his early 40s, had been on the force for nearly 20 years, and died by gas inhalation or drug ingestion. None of these policemen used a gun as a means of committing suicide. The current situation for the United States is more nebulous, as table 2 shows. There seems to be a regional difference in the police suicide patterns in the United States: the east and west coasts seem to have more than the midwest and the south. The use of handguns was the overwhelmingly most common means of self-inflicted death.

According to data from police departments for which additional information was available, the average policeman who suicided was in his late 40s, was divorced or seeking divorce, was at or near retirement after 15 or more years of service, and had difficulties surrounding the use of alcohol. This picture is different from that in London in marital status and the method of suicide.

COMMENT

One interesting sidelight of this research is that it pointed out the difficulty of obtaining consistent and reliable data for useful comparisons among police departments in the United States. The Zilboorg team in New York City had the blessing of Mayor La Guardia for their research activities. Modern police departments, however, have a spectrum of opinions concerning the usefulness of this type of research; consequently, they are often reluctant to admit that such information is available. Even if the information is available, it is usually incomplete. Perhaps the best way to obtain such information in the future is for a

TABLE 1
Suicide Data from the Metropolitan Police Department of London

Suicide	Year	Method of Suicide	Marital Status	Age	Number of Years of Service
1	1960	Not recorded	Married	43	24
2	1960	Not recorded	Married	55	29
3	1960	Coal gas poisoning	Married	47	25

TABLE 2
Suicide Data from Police Departments of 23 Major U.S. Cities*

City	Number of Suicides	Comment
Albuquerque	0	1 former policeman committed suicide
Atlanta	0	"Unaware of any since 1960"
Boston	4	All by handgun
Dallas	0	No suicide of active department member in 20 years
Denver	Unknown	46 officers met violent death between 1890–1971; none appeared to be suicides; 77% were homicides
Detroit	About 1 a year	Information confidential
Honolulu	5	
Little Rock	0	
Los Angeles	Unknown	Department does not keep statistics
Miami Beach	2	". . . during entire existence of department"
Minneapolis	At least 2	No accurate records but at least 2 known
Newark	5	4 by handgun; 1 by drug overdose
New York	About 74	See Heiman (10, 11)
Philadelphia	At least 1	Data not available; 1 by memory
Phoenix	2	1 by firearm; 1 by car crash
Portland	1	5 others who had been retired for a short period of time committed suicide with firearms
Rochester	1	There were others before 1960; 1 after 1960 was by gun
Salt Lake City	0	1 officer killed himself by gun in 1949; he had cancer
San Diego	2	Both by handgun
St. Louis	Unknown	Suicide statistics not available
Seattle	5	All by gun
Topeka	0	
Washington, D.C.	Unknown	No statistical material kept

*Eleven other major cities did not respond to the research inquiry.

physician to become a member of a law enforcement agency and work simultaneously at primary prevention and research (e.g., Bruce Danto [12]).

In spite of the relative paucity of information and the guarded postures of several police departments, some observations can be made. The majority of American police officers used a handgun as the means of suicide. However, it may not be because handguns are used that the suicide rates are high but, rather, that the choice of a handgun reflects patterns of socialization. The use of a handgun is part of the patrolman's work. Marks and Stokes made a similar observation in their analysis of suicide in the south (13). They said their finding that southerners who committed suicide used firearms more often than nonsoutherners and were consequently more successful in killing themselves does not suggest that southerners have a higher lethal intent but that the use of firearms is a function of the

normative patterns of socialization in different regions and sections of the United States.

Although it is tempting to posit a psychoanalytic interpretation of the excessive use of handguns by suicidal police officers, I know of no published study of a large number of suicidal policemen in psychoanalysis that would lend credence to such speculation. Thus the availability of handguns and the inherent socialization process for their use as part of the policeman's work may be the greatest factors in determining the use of a handgun in police suicides in the United States as contrasted to London, where police officers do not carry guns as a rule.

Many psychodynamic formulations have been presented in the literature to account for suicidal behaviors (14–16). Several of these psychodynamic patterns were elaborated by Hendin in his study of the death fantasies and dreams of suicidal patients in analysis (17). One must realize, however, that the psychodynamic patterns of people who attempt suicide might not adequately account for the patterns of those who commit suicide; that is, those who attempt suicide may represent a different population from those who commit suicide (18). Nevertheless, in considering the history of patrolman 42, one can easily ascribe to him Hendin's idea of suicide as retroflexed murder. The intrapsychic processes of this patrolman may have been similar to Stekel's description at the 1910 meeting of the Vienna Psychoanalytic Society:

> *No one kills himself who has never wanted to kill another, or at least wished the death of another. . . .* The secret court of the unconscious follows the principle of talion—"an eye for an eye, a tooth for a tooth"; it declares itself guilty of the death wish and condemns itself to death. (19, pp. 87–89)

For patrolman 43 one can suggest another of Hendin's suicidal mechanisms, i.e., a possible narcissistic injury with death as a process that in an affective sense has already taken place. Although several psychodynamic mechanisms have been suggested to retrospectively and tentatively explain the suicidal deaths of patrolmen 42 and 43, other factors may influence the high suicide rate in some police departments.

Many people consider the role of the police in American society as subsuming criminal investigation and identification and as the vanguard in the war against crime. However, this image greatly underestimates the importance of such nonenforcement roles as social worker, crisis intervener, paramedic, community liaison officer with minority groups, and crime preventer (20). Farber (21) posited that the inability of a patrolman to fulfill these nonenforcement roles, with their caretaker aspects, constant exposure to human misery, and unrelenting demands for "interpersonal giving" and outlays of concern and nurturance, increases the probability of suicide.

One could also consider the modern American policeman as an alienated worker who has little control over the means of production and distribution of law enforcement. That is, legislatures, judges, and lawyers interpret the statutes defining criminal deviance, while the competing pressure groups and lobbying agencies buffet and manipulate the patrolman's use of discretion; these forces are only partially reconciled by political interventions. This situation, coupled with the nonenforcement role demands already described, enables one to readily appreciate that a policeman may, like Goethe's Werther, find no exit from a labyrinth of contradictory forces and choose to die.

Although there appear to be regional variations in suicide rates among police, the individual policeman's life, not a suicide rate, is at stake. Police departments could provide some sort of counseling like that of the Boston Stress Program (22). The policeman's role could also be made less alienated by having community leaders attend to the four basic psychological needs of patrolmen outlined by Denyer and associates (23)—physical security, belonging, efficacy of work, and self-transcendence. Perhaps if these suggestions were implemented, fewer policemen's lives would be lost through suicide.

Inhalant Abuse in an Indian Boarding School

BY MARY F. SCHOTTSTAEDT, M.D., AND JOHN W. BJORK, M.S.W.

The authors describe inhalant abuse among children in an American Indian elementary boarding school. They discuss the initial interventions made to control this problem, such as providing a lower adult-child ratio and improving staff morale and child management skills and developing a volunteer program to improve the quality of the children's experience after school hours. They suggest that such preventive efforts be made early to interrupt the destructive cycle of dependence on external agents.

CASE REPORTS of deliberate inhalation of gasoline vapors by children and adolescents appeared during the 1950s and early 1960s (1–4). In 1962 and 1963 Glaser and Massengale (5) and Massengale and associates (6) drew attention to a rapid escalation of glue-sniffing among adolescents. The majority of their patients (in Denver, Colo.) were boys from large, low-income, disorganized Spanish-American families, who had poor peer relationships, low school achievement, and delinquent behavior. These authors commented on the similarity of these children to adult alcoholic subjects and postulated that many of the boys would shift from glue-sniffing to alcohol use as they grew older. Brozovsky and Winkler (7) and Rude (8) reported alcohol use in the groups of glue-sniffers they studied.

The serious physiological effects of glue-sniffing as well as deaths due to asphyxiation have been documented (9–11). An additional danger for glue-sniffing children is the establishment of habit patterns and ways of coping that foster dependence on external agents. For American Indian children the external agent will most likely be alcohol, a well-documented major problem for these people (12). Particularly vulnerable are Indian groups suffering recent and severe disruptions of their culture and lifestyle, such as the Plains tribes (13). If glue-sniffing is a precursor of alcoholism, identification and treatment of glue-sniffing children becomes an important strategy for preventing alcoholism.

The Bureau of Indian Affairs (BIA) runs 77 boarding schools for American Indians and an additional 18 dormitories from which Indian students attend public schools (14). These schools were originally designed "to separate a child from his reservation and his family, strip him of his tribal lore and mores, and prepare him for never again returning to his people" (15). Children were deliberately sent to boarding schools located far away from their homes, given English names, and forbidden to speak their own languages. The Merriam Report in 1928 urged a fundamental change in these destructive policies (15). However, in 1965 and 1966 Krush and Bjork (16) and Krush and asso-

At the time this work was done Dr. Schottstaedt was Associate Professor of Psychiatry and Medicine, University of Oklahoma College of Medicine, Oklahoma City, Okla. She is now Associate Professor, Division of Community and Social Psychiatry, University of Texas Medical Branch, Galveston, Tex. 77550. Mr. Bjork is Chief, Mental Health and Social Service Branch, Oklahoma City Area Indian Health Service, U.S. Public Health Service, Oklahoma City, Okla.

The authors would like to thank the school staff and their colleagues for their cooperation and assistance. They would especially like to thank the volunteers, Nancy King Robinson, Ronald Robinson, Gary Harris, Joann Carpenter, Patricia McKnight, Glen Smith, Mel Harris, Jan Bravo, and Dr. and Mrs. Joseph Ferretti.

The opinions expressed in this paper are those of the authors and do not necessarily reflect the views of the Indian Health Service.

ciates (17) documented the continued deleterious impact of the boarding school experience on Indian children.

One effort to improve the well-being of Indian boarding school children was instituted in 1967—the model dormitory project on the Navaho reservation (18). Decreasing the adult-child ratio, training counselors in child care techniques, and developing pride in the Indian heritage resulted in positive effects on the intellectual, physical, and emotional development of model dormitory children (19, 20). However, this project has been terminated.

THE INDIAN BOARDING SCHOOL

The school reported on in this paper is one of two BIA elementary boarding schools in the state of Oklahoma. It was founded in 1871 to serve children of the Western Plains tribes, which were defeated and confined to reservations about 100 years ago after more than a century of independent, nomadic, warlike existence in a buffalo-hunting economy. The Dawes Act of 1887 reduced the amount of land assigned to Oklahoma Indians by awarding each Indian 160 acres and allotting the remainder for white settlement (21). Oklahoma Indians continue to live throughout the state, not on reservations. The Indians are an impoverished group largely dependent on unskilled employment or forms of relief. In the 1972–1973 school year, 90% of the children enrolled in our school came from western and central Oklahoma.

Data on our students were gathered by direct observation, participation in staff meetings, and interviews with staff members over a 2-year period (1972–1974). One of us (M.F.S.) served as psychiatric consultant to the Indian Health Service Unit and was asked by the school superintendent to consult at the school one day a month. We regarded this as an opportunity to initiate primary and secondary prevention (as defined by Caplan [22]) in a circumscribed, high-risk, young population group. Although glue-sniffers were the focus of our attention because of the hypothesized relationship between glue-sniffing and alcoholism, our overall goal was to alter the boarding school experience favorably for all of the children.

The school's capacity was 256 students in grades 1–8. Total enrollment for a school year ran around 350. Although the sole criterion for admission was that a student be at least one-quarter Indian, most children came to the school because of serious family disruption. Eighty of the 291 children enrolled by November 1973 (27%) had last names different from their next of kin's. Academic deficiencies were demonstrable in many students. More than 33% of the children in grades 4–8 were reading 2 or more years below their grade level.

The school was located on a prairie in western Oklahoma 40 miles west of the state capital. The physical plant, completed in 1968, had school rooms using open space with learning centers that were well-equipped with modern learning devices and resources. Indian heritage was emphasized in the classrooms.

The dormitories were one-story buildings separate for boys and girls. According to their age, 4 children were assigned to one sparsely furnished room from which the doors had been removed. None of the children had any personal possessions. Even clothing was kept in a central laundry area and doled out as needed. In contrast to the classrooms, nothing about the dormitories indicated the Indian heritage. Although the large central living and recreation rooms were always accessible, hobby rooms and kitchenettes were kept locked because of the limited number of staff. Food was served cafeteria-style in a separate building with no chance for selection. Children ate at long tables separated from the staff. Evening snacks were rarely available except from coin-operated candy and soft drink machines.

The dormitory staff included 4 college-educated supervisors and counselors (3 of whom were Indian) and 18 Indian aides charged with the immediate care of the children and their living area. Two aides were on duty at a time, resulting in an adult-child ratio of 1:64. To keep order, supervise housekeeping tasks, and meet the many physical needs of 64 children was an overwhelming assignment, leaving little time and energy to meet the emotional needs of the youngsters. Aides could be observed to retreat to their glass-walled offices as children poured into the dormitories after school. The aides posted written directions such as "Go take showers" on the glass wall. They were constantly responding to crisis situations, and they were frustrated because physical punishment, which they had experienced as boarding school students, was strictly forbidden. They could give "hours" for misbehavior, but then they had to see that children "worked off" the hours. There was no system of rewards.

Children not only brought to school overwhelming personal problems and needs but found themselves in a setting in which problems of group living were rampant. A pecking order was quickly established; status was maintained by brute force. A negative value system was promulgated: those who did well academically tended to drop out due to harassment. Scapegoating was common, and peer pressure to participate in mischief, including glue-sniffing, was ever present.

INHALANT ABUSE AND INTERVENTIONS

It is difficult to accurately document such behavior as glue-sniffing even in a boarding school population. In November 1973 2 counselors identified 37 habitual sniffers among 291 students enrolled that fall (12.7%). According to a personal communication from T. Voskuhl at the National Institute on Drug Abuse, it is reasonable to assume that the actual number was higher. The children identified as glue-sniffers included 11 girls and 26 boys in grades 6–8 (4 in grade 6, 13 in grade 7,

and 20 in grade 8). Sixteen of these children had last names different from their next of kin's (43%, compared with 27% of the total school population). An additional 4 of these children used alcohol habitually, and 15 were chronic smokers.

Other kinds of escapist behavior erupted in the fall of 1973. Nineteen girls engaged in knocking themselves out by twisting towels around their necks. Children obtained spray paints, glue, and solvents for sniffing from stores in nearby towns and the maintenance shop on campus. They stole gas from unlocked gas tanks of cars or tractors in adjacent fields. They tried shoe polish, ink, lighter fluid, and nail polish remover. The gas jets in the science classroom had to be disconnected because children used them to fill plastic sacks for sniffing. Supplies were hidden ingeniously in dormitory rooms—in vents, light fixtures, beds, and behind molding or paneling. Sniffing was usually a group activity done in nearby woods or after lights out in dormitory rooms.

School staff had already taken steps to limit the accessibility of inhalants through locking up supplies and car gas tanks. Plastic sacks were cut up before being discarded. A local Indian youth organization conducted campaigns to get stores in nearby towns to stock paint and glue supplies out of reach because sniffing was also a problem among public school children.

Our additional methods of intervention were based on the premise that glue-sniffing is a symptom of emotional distress resulting from multiple deprivations. We sought ways to meet basic emotional needs more adequately and to provide nondestructive mechanisms for release of tensions. Decreasing the adult-child ratio and improving staff morale and child management skills were initial steps. The staff schedule was changed to maximize coverage in evening hours. One of us (M.F.S.) met regularly with girls' dormitory aides to explore specific problems. Permission was granted for a social worker from the state's drug abuse program to spend one afternoon a week at the school seeing individual children in counseling sessions. The superintendent and counselors supported the development of a volunteer program in which 10 students and faculty from the Oklahoma Health Sciences Center participated. All of the volunteers attended weekly supervisory sessions; the medical students in the group were given elective credit for these sessions. The volunteers spent one evening a week in dormitories getting to know children individually and participating with them in recreational activities and at the evening meal. They introduced new games, crafts, and reading materials. Despite the prediction that books would be destroyed if left in the dormitory, 37 of the 40 books placed in the boys' dormitory were accounted for at the end of the year. The volunteers furnished new kinds of interpersonal experiences and role models for both students and aides. Ultimately, the school staff obtained permission to hire two Indian recreation directors. Their presence allowed evening use of the gymnasium and school library as well as further expansion of sports, arts, and crafts programs.

The counselors commented that there was less sniffing after the volunteer program was initiated than there had been in previous school years. By March 1974 only 5 additional children had been identified as sniffers. Counselors initiated the effort to hire the two recreation directors. Thus, indirect evidence supported the value of the program. Despite tribal antipathy toward research, school staff and tribal leaders cooperated in developing a research and demonstration grant proposal. Funds from this source are now supporting a research project to study the problem of sniffing and the effects of additional interventions.

DISCUSSION

Background factors known to be associated with inhalant abuse were readily identifiable in these Indian boarding school children: minority status, cultural upheaval, low socioeconomic level, family disruption, significant losses, neglect, delinquency, and poor school achievement. In addition, the boarding school experience itself compounded their problems: they were separated from their families and their home communities and placed in an institutional setting. Serious interpersonal deprivation occurred due to the limited number of dormitory aides and the impossible demands made on them. Organized recreational activities were inadequate. These children were denied the usual accoutrements of a home, toys, personal possessions, and reading materials. In such a setting, inhalant abuse offered solace, escape, entertainment, camaraderie, prestige, and gratification. Peer pressure enabled it to spread like a contagious disease.

All of these children needed to relate to warm, accessible, caring adults. They needed a chance to develop individuality, self-esteem, and pride in their Indian heritage. With one day a month of psychiatric consultation time available, the challenge was to set in motion some mechanism to change the system. Although a few identified sniffers were singled out for separate management, their environment was our prime focus of attention. Two main means of intervention were used: improving the morale and child management skills of existing staff and finding additional sources of adult contact through whom to introduce new attitudes and ideas. The latter included the development of a volunteer program, which had additional potential for interesting health care professionals in the needs of American Indians; and identifying additional sources of funding to improve the quality of the children's experiences in after-school hours. The active cooperation of school and health service staff was forthcoming in this quest.

The boarding school experience of American Indian children can be modified to provide healthier influences on the emotional growth and development of these students. Dependence on external agents is a

major problem for American Indians. Preventive efforts must start early to interrupt the destructive cycle that perpetuates family disruption and consequent boarding school rearing for yet another generation.

This section contains reports of new clinical or laboratory observations, single cases of unusual interest or importance, descriptions of pilot studies, suggestions for future research, etc. Reports should be submitted in duplicate, typed double-spaced throughout, and may contain 1,000 words, no more than 1 table, and a maximum of 10 pertinent references. Figures cannot be used. Reports will be reviewed by at least one referee and the Editor; the author will receive a postcard informing him/her of the disposition of the submission. Reports will be edited for clarity and conformance with Journal *style.*

Timing and Risk of Bone Marrow Depression by Psychotropic Drugs

BY LAURENCE DUCOMB, M.D., AND ROSS J. BALDESSARINI, M.D.

We recently encountered a case that illustrates the clinically important point, accepted in good medical practice but rarely documented, that the period of risk for the suppression of bone marrow function by a medication begins anew each time another agent is introduced in the treatment. In addition, we will present further data to support the impression that severe depression of bone marrow function ascribable to psychotropic agents, while potentially life-threatening, is unusual.

Case Report

A 21-year-old male bank teller with no previous psychiatric illness developed an acute psychotic illness characterized by agitation, grandiosity, paranoid delusions, and auditory hallucinations. His mother had had recurrent depressions. He was admitted to our general hospital psychiatric service and treated for a month with haloperidol, 30–50 mg/day. Neurological and general medical examinations, including leukocyte counts, were normal during that period. In the second month of treatment with haloperidol he developed increasingly bothersome motor restlessness (akathisia), which disappeared after discontinuation of the butyrophenone. However, a week later his mental status deteriorated markedly. Thioridazine (600 mg/day) was used for 2 days but was ineffective. The medication was changed to chlorpromazine in increasing doses up to 2000-3000 mg/day, with a good response over the next 6 weeks. At that point, the patient complained of malaise and sore throat. Since the total time of exposure to neuroleptic agents had been almost 3 months and since this young man was not considered to be at high epidemiologic risk for agranulocytosis, it was somewhat surprising that a leukocyte count was only 1,600 cells/mm^3. Chlorpromazine was stopped and the patient was immediately transferred to a medical intensive care unit. The white blood cell count (WBC) continued to fall for several days to 400 cells/mm^3, with no granulocytes in the peripheral blood and a hypoplastic iliac bone marrow containing some myeloblasts. There were only small decreases in circulating erythrocytes and platelets and their marrow precursors. Fever and staphylococcal skin infections were treated with antibiotics. For 10 days his clinical condition remained precarious. Then, over 72 hours, immature granulocytes appeared in the blood and the hematologic condition returned toward normal. His psychiatric status remained stable enough to permit continued withholding of antipsychotic medication.

Discussion

This case illustrates the point that one must be alert to the possibility of toxic suppression of the bone marrow for at least several weeks following the initiation of treatment or *after a change to a new agent* and whenever the medical picture presented by this case is encountered. Antipsychotic agents, especially low-potency phenothiazines (notably chlorpromazine), are

Dr. DuComb is Assistant Resident in Psychiatry, Massachusetts General Hospital, and Dr. Baldessarini is Associate Director, Mailman Laboratories for Psychiatric Research, and Associate Professor of Psychiatry, Harvard Medical School and McLean Division of Massachusetts General Hospital. The work was partially supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-25515 from the National Institute of Mental Health and by NIMH Career Scientist Award MH-74370 to Dr. Baldessarini.

The authors wish to thank Ms. H.L. Sequeira, Massachusetts General Hospital, Medical Records Research Department, for skillful assistance with recorded data.

among the psychotropic agents most commonly associated with drug-induced agranulocytosis (1–3). The reported period of maximum risk is at about 3–4 weeks but continues to at least 8–12 weeks (1–3). Since this reversible condition evolves rapidly over a few days and is potentially fatal secondary to sepsis, a high index of suspicion, immediate discontinuation of drug treatment with appropriate medical treatment can be life-saving. Occasional routine WBCs are rarely helpful in predicting agranulocytosis (1, 3).

The current incidence of frank agranulocytosis or serious leukopenia during treatment with psychotropic agents is not clear. Previous estimates for the phenothiazines have been as low as 1/250,000 with short-term treatment (1, 3), but rates of about 1/1,000 to 1/2,000 have been typical in many surveys of the 1960s (1–3), and the figure may be higher in older patients (especially women) exposed to high doses of low-potency phenothiazines for prolonged periods. Similar reactions to other antipsychotic agents and to the chemically related tricyclic antidepressants have been reported very infrequently, possibly because of the use of smaller doses than of the low-potency phenothiazines and the typically short-term exposure to antidepressants. Leukopenia has been only rarely associated with other psychotropic agents such as the sedative-tranquilizers (1). Recent studies have suggested that the incidence of agranulocytosis associated with antipsychotic drugs may be lower than was reported previously. For example, only 1 case associated with chlorpromazine plus imipramine (and 3 other cases of milder leukopenia) was found in a 1,552-bed psychiatric hospital under careful surveillance in 1968 (4). More recently, only 1 or 2 cases possibly associated with phenothiazines were found in 1972 in a total population of 44,430 medical and psychiatric outpatients (5), although the number of patients actually at risk (i.e., exposed to phenothiazines) was not stated.

In the course of the present study we obtained, by a computer-assisted search, information on all instances of leukopenia associated with any medication in the period 1969–1976 (360 cases) among all patients admitted to the Massachusetts General Hospital. In most cases the probable cause of the bone marrow suppression remained obscure. Of the 91 cases we found that bore a highly probable association with specific medications other than cytotoxins (chemotherapy in cancer and organ transplantation), more than half were associated with antibiotics and almost 40% with various other drugs. Including the present case, we found only 5 patients with significant leukopenia (WBC below 4,000) associated with antipsychotic or antidepressant drugs, and only the present one had "frank agranulocytosis" (WBC well below 3,000) as defined by Pisciotta (2). One other patient had counts as low as 2,900 with very small doses of chlorpromazine (25 mg h.s.) plus alphamethyldopa. Of the 3 other cases, 1 involved a WBC close to 3,000 following small doses of chlorpromazine, a second had very mild transient pancytopenia associated with imipramine, and a third involved WBCs between 4,000 and 5,000 in an 81-year-old woman given amitriptyline. Thus, at most, there were only 2 cases that might be considered agranulocytosis (including the present one), and both were possibly associated with chlorpromazine. The population at risk is unknown since we could not determine how many patients were exposed to antipsychotic or antidepressant agents, but the total number of patients (out of 233,610 admissions) from whom this group was gathered was estimated to be 205,554, suggesting that the problem either occurs infrequently or is infrequently noted in the record. Arguing against the latter hypothesis was our observation of extremely assiduous hematologic evaluation of relatively mild leukopenias, which might be expected in a teaching hospital.

Although these results and recent observations of outpatients (5) cannot provide true incidence figures because the number of patients at risk by exposure to the drugs in question is unknown, they suggest that the incidence of serious leukopenia associated with antipsychotic and antidepressant drugs may have been declining since the late 1960s. Such a change might reflect an increased use of high potency (low dose) neuroleptic agents in recent years. Although it is not clear that the incidence rises in a close relation to daily drug dosage, it seems to increase as a function of the dose-time interaction (1, 2). Moreover, the current trend toward increasingly high doses of antipsychotic medications and prolonged use of antidepressants may increase tissue pools of slowly cleared potentially toxic drugs and might, if continued, eventually lead to higher incidence rates of agranulocytosis.

Proven Asymptomatic Eosinophilia with Imipramine

BY NEAL R. CUTLER, M.D., AND DOUGLAS J. ANDERSON, M.D.

The *Physicians' Desk Reference* lists eosinophilia as a potential adverse reaction to imipramine, but a survey of the literature revealed only three reports of this response. Penick and Carrier (1) described a case of asymptomatic eosinophilia accompanied by leukocytosis during imipramine therapy. The total white cell count reached 23,200 with 56% eosinophils; 8 days after withdrawal of imipramine the count had decreased to 6,400 with 12% eosinophils. Joynt and Clancy (2) reported on a patient who showed a maximum total white cell count of 30,000 with 61% eosinophils during treatment with imipramine. When the patient developed a stiff neck, severe generalized headache, and nausea, imipramine was discontinued. Results of a lumbar puncture were normal and the symptoms abated within 2 days. By the 25th day after imipramine was discontinued, the total white cell count had decreased to 11,500 with 3% eosinophils. Hippius (3) followed the relative eosinophilia in 25 patients treated with imipramine. During 9 weeks of administration of the drug the relative percentage of eosinophils peaked at an average of 4% at 6 weeks and returned to the pretreatment average level of 2% by the end of the 9 weeks. Data for individual cases were not provided, and generalized leukocytosis was not mentioned.

All of these reports were either based on coincidental rise and fall of the eosinophil count during imipramine therapy or coincidental decline of a marked eosinophilia on withdrawal of the drug. The case we will describe, in which we followed the eosinophil count through two consecutive periods of imipramine administration separated by a drug-free interval, is to our knowledge the first to confirm in this way the correlation between imipramine and asymptomatic eosinophilia.

Case Report

A 57-year-old man was admitted to the hospital following a suicide attempt. A diagnosis of psychotic depression was made based on a 6-week history of depressed affect, feelings of worthlessness and hopelessness, and vegetative signs and symptoms, including insomnia, anorexia (6.8-kg weight loss), constipation, psychomotor retardation, and decreased libido. Physical examination on admission was within normal limits. On the 2nd hospital day the patient was started on 75 mg of imipramine, increased over the next 6 days to 300 mg/day. On the 12th hospital day the patient developed a nonproductive cough with chest pain. His CBC revealed a total eosinophil count of 10,750, or 45% of the total white count of 23,900.[1] A diagnosis of viral pneumonia was made, and the eosinophilia was thought to be Löffler's syndrome (pulmonary infiltration with eosinophilia), eosinophilic leukemia, or secondary to imipramine therapy.

The pulmonary symptoms and physical findings resolved in a few days, but the eosinophilia persisted. An extensive medical workup was undertaken, including bone marrow aspiration and biopsy, bronchoscopy with bronchial biopsy, and whole body gallium scan. These studies ruled out any suspected neoplastic disease. Other studies were done to rule out parasitic infestation and collagen vascular disease. The bone marrow aspiration showed 51% eosinophils. Pulmonary symptoms cleared in a few days and a chest X ray was normal, but because of persistent depressive symptoms imipramine was continued after resolution of the pneumonia to the 27th hospital day. At that time the total white cell count was 17,500 with eosinophilia having reached a maximum of 66% (11,550 total eosinophil count).

Two days following discontinuation of imipramine, leukocytes and eosinophils had fallen to 8,800 and 32%, respectively (2,830 total eosinophil count). Nine days after discontinuation the total white cell count was 6,100 with 10% eosinophils. The patient was discharged and healthy on the 47th day on no medication. Seven days later the white count was 7,300 with a normal eosinophil count (140 total). In order to confirm our impression of drug-induced eosinophilia, the patient gave informed consent to restart 100 mg of imipramine daily as an outpatient. One month later on a dose of 250 mg/day the white cell count was 7,000 and the eosinophil count had again risen to a high of 11%.

Discussion

The incidence of asymptomatic eosinophilia with imipramine is unknown. Our case adds to the reported occurrence of a marked or relative eosinophilia with this drug. Moreover, this is the first case we know of to confirm a causal relationship by a second course of administration. It is of interest that there was no total leukocytosis in the second course compared with the first, and the eosinophilia was only 15% as severe. This diminished eosinophilia response with a repeated administration of the drug is unlike that seen with certain other drugs. For example, gold therapy in rheuma-

Dr. Cutler is Resident in Psychiatry and Dr. Anderson is Supervising Staff Psychiatrist and Clinical Instructor in Psychiatry and Human Behavior, University of California, Irvine/Long Beach Veterans Administration Hospital, Long Beach, Calif. 90822.

[1]The normal range of total eosinophil count at our hospital is 0–450.

toid arthritis has been shown to produce a type 1 hypersensitivity reaction. The eosinophilia response in these patients remains about the same with a repeated administration of gold (4). Our case suggests a gradual desensitization to imipramine-induced eosinophilia with repeated administration. Although the precise mechanism behind asymptomatic eosinophilia with imipramine is unclear, our case leaves no doubt that it does occur.

A Case of Oral Dyskinesia Associated with Imipramine Treatment

BY JEFFREY J. DEKRET, M.D., IRADJ MAANY, M.D., T. ALAN RAMSEY, M.D., AND JOSEPH MENDELS, M.D.

Reports of oral dyskinesias associated with the administration of antidepressants are scarce. There have been reports of choreoathetoid movements as a toxic manifestation of acute tricyclic antidepressant poisoning (1) and of two patients who developed dyskinesia while receiving tricyclics concurrently with neuroleptics (2). The following case strongly suggests a causal relationship between imipramine treatment and an oral dyskinesia.

Case Report

The patient, a 52-year-old man, was hospitalized for complaints of depression, nervousness, diminished appetite with a 7-kg weight loss, and guilty ruminations that had persisted for over a year. There was no evidence of manic disorder, alcohol or drug abuse, formal thought disorder, or organic brain syndrome. Six months before his admission, the patient had been hospitalized elsewhere for 10 weeks and had been given haloperidol, 0.5 mg t.i.d., which he was still taking at the time of his admission. He had not taken any other psychotropic medication for years. The patient also had a history of hypertension that had been treated with methyldopa and hydrochlorothiazide for the preceding 3 years.

Physical examination, including a neurological workup and laboratory studies, was unremarkable on admission. The patient received no active medications for the first 3 weeks in the hospital and he remained significantly depressed (17-item Hamilton Rating Scale scores were in the mid-20s). Imipramine HCl, 100 mg/day, was started and increased by 50 mg every other day until a dosage of 250 mg/day was reached. Three days after the 250-mg dosage was started, the patient developed abrupt involuntary buccal contractions about every 5 seconds while speaking. These contractions apparently involved the soft palate, larynx, and diaphragm and disturbed his speech. His symptoms were worse when he was anxious but slight and infrequent when he was not speaking. A fine tremor of the tongue and involuntary tongue rolling and lip licking were present at rest. There was also a fine resting tremor of the upper extremities. During sleep he had myoclonic jerks of his extremities and grimacing, chewing motions that resulted in mouth ulcerations.

A neurology consultant noted no other findings and felt the condition was related to the medication. The patient was videotaped twice weekly while the condition was severe and weekly when it improved. Physostigmine, 1 mg I.V., was given intravenously over a 5-minute period during one videotaping, and the abrupt oral contractions almost disappeared for an hour. Other signs mentioned above were difficult to evaluate because of rapidly emerging signs and symptoms of cholinergic excess, which required atropine administration.

The patient had an excellent response to imipramine, so it was decided to reduce the imipramine dosage rather than change medications. Two weeks later, on a dose of 150 mg/day, the speech disturbance had disappeared, but the fine tremor of the tongue and upper extremities, tongue rolling, and lip licking persisted. One week later, on 100 mg/day, only the fine movements of the tongue remained. The next week the imipramine dosage was increased to 250 mg/day over 3 days. His oral dyskinesia reappeared but was less severe. The imipramine was again reduced to 150 mg, and the dyskinesia disappeared within a week. The patient was discharged on this dosage, and there was no recurrence of the dyskinesia or depression after 6 months.

The authors are with the Department of Psychiatry, University of Pennsylvania School of Medicine and the Veterans Administration Hospital, Philadelphia, Pa., where Dr. Dekret was Research Fellow, Dr. Maany is Associate, Dr. Ramsey is Assistant Professor, and Dr. Mendels is Professor of Psychiatry and Chief, Depression Research Unit. Dr. Dekret is now Clinical Instructor, Department of Psychiatry and Human Behavior, Jefferson Medical College, Philadelphia, Pa. Address reprint requests to Dr. Mendels at the Veterans Administration Hospital, 151E, University and Woodland Avenues, Philadelphia, Pa. 19104.

Discussion

The oral dyskinesia described herein appears clinically very similar to tardive dyskinesia, and we hypothesize a similar pathogenesis. Current theories regarding the pathogenesis of tardive dyskinesia rest on the emergence of denervation supersensitivity of dopamine receptors following the prolonged blockade of these receptors by neuroleptics (3). This leads to a relative hyperdopaminergic and hypocholinergic imbalance in the basal ganglia (4).

The same imbalance may have developed in this patient. Supersensitivity of dopamine receptors may have developed from the previous haloperidol treatment or even from the mild postsynaptic dopaminergic blocking properties of imipramine (5). Finally, the strong anticholinergic properties of imipramine could increase the relative hyperdopaminergic-hypocholinergic imbalance sufficiently to produce the described oral dyskinesia. Imipramine seems to be the primary causal agent because the onset and severity of the dyskinesia correlated with the onset of treatment and the dosage of imipramine.

L-Tryptophan in Obsessive-Compulsive Disorders

BY JOSE A. YARYURA-TOBIAS, M.D., AND HEMMIGE N. BHAGAVAN, PH.D.

Obsessive-compulsive disorders are usually characterized by dwelling on thoughts that one cannot reject, inability to make decisions, rituals (e.g., hand washing), double-checking, and repetitive questioning. Secondary symptoms are anxiety, depression, and hostility. The etiology of the obsessive-compulsive disorders is believed to be psychological (1), but psychobiological treatments have failed to yield satisfactory responses. We have had success in clinical trials using chlorimipramine, a potent serotonin (5-HT) reuptake blocker (2). Further studies supported our hypothesis that some obsessive-compulsive disorders are organic in nature and may be related to a central disturbance in 5-HT metabolism (3). In this paper, we will report on the clinical efficacy of the precursor amino acid L-tryptophan in obsessive-compulsive disorders.

Method and Results

Seven obsessive-compulsive patients (4 male and 3 female) ranging in age from 13 to 40 (mean=22.9 years), gave informed consent to participate in the study. Subjects were placed on L-tryptophan, 3 to 9 g (mean=6.28) daily in divided doses given orally. In addition, all patients received oral daily divided doses of nicotinic acid, 1000 mg b.i.d., and pyridoxine HCl, 200 mg b.i.d. The patients showed considerable improvement after 1 month of therapy and after 6 months to 1 year of therapy their conditions were stabilized. In 2 cases in which there was a history of aggressive behavior, such behavior increased after L-tryptophan administration (doses of 3 g and 7 g, respectively). One patient who was given 5 g/day of L-tryptophan experienced headaches.

Discussion

The data presented here demonstrate the therapeutic effectiveness of L-tryptophan in controlling obsessive-compulsive symptoms. The rationale for the use of L-tryptophan was based on our successful experience with chlorimipramine in obsessive-compulsive disorders. Chlorimipramine is a potent 5-HT reuptake blocker and its effect therefore is presumed to be mediated by a serotonergic mechanism. There are other means by which an increase in the steady state levels of serotonin in specific areas of the brain may be accomplished. In this study, we took the approach of using the naturally occurring amino acid L-tryptophan, a precursor of 5-HT. Serotonin synthesis in the brain is regulated by the availability of this amino acid (4, 5), so an increased synthesis may be expected after administration of an excess of the precursor. To ensure that significant amounts of tryptophan would be available for 5-HT synthesis, we also used nicotinic acid supplements. It has been shown that excess nicotinic acid can inhibit the major metabolic pathway of tryptophan by way of tryptophan pyrrolase and thus make more tryptophan available for 5-HT synthesis (6). Be-

Dr. Yaryura-Tobias is Director of Research and Dr. Bhagavan is Director of Biochemical Research, North Nassau Mental Health Center, 1691 Northern Blvd., Manhasset, N.Y. 11030.

cause pyridoxine, as the coenzyme pyridoxal-5'-phosphate, is involved in numerous pathways related to amino acids, neurotransmitters, etc. (7), it was considered helpful to provide adequate quantities of this vitamin in the treatment regimen.

The observed increase in the aggressive behavior of two patients is similar to our previous unpublished findings with aggressive patients who were given tryptophan. We can only speculate, in the absence of pertinent biochemical data, that it is the tryptophan per se or the balance between tryptophan and 5-HT that may regulate aggressive behavior. An imbalance may precipitate or exacerbate the aggressive behavior. Whatever the mechanism, our experience indicates that tryptophan treatment in such patients is contraindicated.

The data obtained in this preliminary study are very encouraging and suggest the potential use of this type of approach in other disorders.

Pediatric Bone Marrow Transplantation: Psychosocial Aspects

BY BETTY PFEFFERBAUM, M.D., M. MURIEL LINDAMOOD, M.S.W., AND FRANCES M. WILEY, R.N.

Many authors have investigated the multifaceted impact of serious childhood illness (1–6). One recent article addressed the emotional stress of bone marrow transplantation in adults and adolescents (7). In our experience with children undergoing the bone marrow transplantation procedure, we have been equally impressed with the importance of psychosocial factors in this highly vulnerable age group.

The procedure involves supralethal doses of radiation and chemotherapy. The destroyed bone marrow is then replaced by an infusion of marrow from a compatible donor. The process and the expected complications of graft-host disease, infection during marrow suppression, bleeding, and toxicity from radiation and chemotherapy necessitate a lengthy and complicated hospitalization (mean=8.8 weeks). The child spends most of his/her time in reverse isolation, frequently in a critical condition (8, 9).

Nineteen children between the ages of 7 and 16 received bone marrow transplants at the University of California, Los Angeles, from 1973 through 1976 for aplastic anemia and leukemia. Because of the high mortality rates for these diseases (approaching 100% without this procedure), bone marrow transplantation was often considered the last hope in an otherwise hopeless situation. Five children died during the procedure.

From its inception the transplant team emphasized attention to the psychosocial aspects of care. As we gained more experience in working with those involved with the procedure, it became clear that an increasingly vigorous participation of mental health personnel could be of significant benefit in dealing with the intense emotional stress involved. Consequently, a child psychiatry consultant joined the social worker and nurses as a regular participant in the weekly transplant rounds held by the oncologists. In addition, case-centered and issue-centered psychiatric conferences were held in which the entire staff had the opportunity to discuss their feelings of frustration with problem areas, intrastaff conflicts, and the ever difficult emotional aspects of working with terminally ill children and their families. In addition, support services such as play therapy and a schoolteacher were readily available. Physical therapy, dietary, and professional services were all geared to the needs of children. Weekly thanatology conferences gave the transplant team an opportunity to view pediatric death in a larger framework.

An objective assessment of all those involved in the

care of the children was not possible. We decided to focus our investigation on the parent-child interaction, although we also collected many subjective impressions of all those concerned. We chose this focus because in the day-to-day life of the hospitalized child the familial interaction seemed to play so large a part in the child's well-being. We suspected that family interaction and involvement might be predictors of the child's survival during the procedure. In order to determine whether emotional factors had a direct bearing on survival, retrospective subjective ratings were done by the physicians, nursing staff, and social worker on various aspects of family interaction. Parents were rated as to the frequency of visiting, the degree to which they seemed to offer emotional support to the child, and their general enthusiasm for the procedure. In addition, the child's motivation for the procedure was rated. Data were analyzed by chi-square with Yates' correction.

None of the factors investigated was found to be a significant predictor of survival, either during or after hospitalization. We speculate that the overwhelming nature of the illness far outweighed any other single factor.

Although the psychosocial factors did not affect outcome in terms of survival, we believe that these factors were critical in the management of many cases. Therefore, even though direct correlations between survival and psychosocial factors could not be demonstrated, we strongly suspect that psychosocial factors may have had an indirect influence that was difficult to measure. Certainly, the team's awareness of such factors improved their management of these children and their families as is illustrated in the cases discribed below.

Case Reports

Case 1. Bobby came from a highly disturbed family with an alcoholic father and a histrionic mother. The parents' ambivalence toward the procedure, especially manifest in times of crisis, led to such drastic intrafamilial interactions that they were unable to support the patient.

Although he was only 10 years old, Bobby gave an initial impression of maturity and control. We considered this to be an adaptive response to a long struggle with leukemia. However, we later recognized this adaptation to be a shaky construct of fragile defenses.

Bobby suffered a very stormy course, during which it was difficult to distinguish physical from psychological components. Problematic signs and symptoms included anorexia, hematemesis, and blurred vision. Behavioral symptoms included rage reactions, hiding under his blankets, and major control struggles over activities, medications, and even staff assignments. He interfered with medical management by turning off his I.V. line and refusing venipuncture. Bobby displayed the fragility of his defensive structure when he related elaborate fantasies and dream material to the child psychiatrist.

After much persistent team effort, a sufficient modicum of cooperation was obtained from the parents and the patient to permit improved medical management. Bobby survived the transplantation. We feel, although we cannot prove it conclusively, that the team effort contributed to his survival.

Case 2. Susan's parents had a strong marriage, seemed to share responsibilities, and agreed fully about the decision for her transplantation. Susan's home was many miles from the medical center, so the parents decided that her mother would move to Los Angeles to be with Susan while the rest of the family remained at home. Family "reunions" were held every weekend in Susan's hospital room, and she received a call from home every night.

The mother's insight enabled her to convey to the staff both Susan's and her own needs. This became a positive working relationship in which the staff focused on helping the mother to care for her own child. Susan allowed the child psychiatrist only occasional glimpses of her fears of death, but she confronted her mother directly with these fears. Her mother was able to seek guidance and support from the staff and the child psychiatrist worked with her to help Susan deal with her fears and concerns. In this case, the team was able to channel the positive forces already present and thereby further ensure smooth medical management.

Conclusions

We have observed that attention to psychosocial factors favorably affects medical management of children undergoing bone marrow transplantation. We reasoned that the attention paid to these factors might well affect mortality rates during and/or after hospitalization, particularly after the addition of a child psychiatric consultant to the team. Our pilot study of 19 children focused on parent-child interactions, which seemed of paramount importance. No statistically significant correlation could be made in this small sample between psychosocial factors of parent-child interaction and survival rates for the procedure or the post-hospitalization course. However, since we were clinically impressed by the salutory effect of psychosocial intervention on medical management, we postulate that a larger, more detailed study using other measures might demonstrate a direct or indirect effect on mortality rates, at least with respect to survival of the procedure itself.

The Effect of Benztropine Mesylate in the Rabbit Syndrome and Tardive Dyskinesia

BY ROBERT SOVNER, M.D., AND ALBERTO DIMASCIO, PH.D.

The "rabbit syndrome," a term coined by Villeneuve (1), is a late-onset neuroleptic-induced extrapyramidal syndrome characterized by rhythmic 5–5.5 per second involuntary movements of the oral and masticatory musculature that mimic the chewing movements of a rabbit (2). The rabbit syndrome is readily reversible when neuroleptic drug therapy is discontinued (1), and it responds to antiparkinsonian drug therapy (1, 2) These clinical characteristics and the experimental observation that the rabbit syndrome persists during stage I non-REM sleep while tardive dyskinesia does not (2, 3) suggest that the former is a distinct neuroleptic-induced extrapyramidal syndrome and not just a form of the latter. The following case report provides additional support for this hypothesis.

Case Report

Ms. A, a 54-year-old single woman, has had eight psychiatric hospitalizations in the past 10 years for a late-onset paranoid psychosis and has received approximately 8 months of intermittent drug therapy with several different neuroleptic agents. She has no history of neurological illness and has not received ECT.

Involuntary movements were first noted at the time of her most recent hospitalization for treatment of her recurrent psychosis. On the day of admission she was given fluphenazine decanoate, 25 mg I.M., and within several days her psychotic symptoms resolved and the involuntary movements decreased in severity. She was discharged on the fifth hospital day and was referred to the Tardive Dyskinesia Clinic. At each clinic visit, her involuntary movements were assessed by R.S. on the Abnormal Involuntary Movement Scale (AIMS), developed for use in the National Institute of Mental Health Collaborative Study of Fluphenazine Decanoate. The severity of rabbit syndrome movements, when present, was assessed with a global rating scale using the same anchor points employed in the AIMS. Results of ratings are presented in table 1.

At her first clinic visit a definite diagnosis of tardive dyskinesia was made by R.S. on the basis of undulating (myokimic) tongue movements, involuntary chewing movements, and axial hyperkinesia (all of mild severity). There was also a suggestion of perioral involvement. The severity of her dyskinetic symptoms was increased by arousal. The patient was not aware of the movements. She was requested to return in 2 weeks for reevaluation.

When she returned to the clinic, the patient reported that she had gone to an emergency room 3 days after her last visit when severe mouth movements suddenly developed. The doctor on call prescribed benztropine mesylate, 2 mg b.i.d., and these movements disappeared within 2 days. Examination in the Tardive Dyskinesia Clinic revealed that the tongue movements were of moderate severity. Perioral movements were definitely present and choreoathetoid movements of the extremities were observed for the first time. There was no sign of the new movements for which she had been treated. The patient was told to discontinue the benztropine mesylate.

She returned to the clinic 8 days later in acute distress. Mouth movements identical to those for which she was given the benztropine mesylate had returned, involving the masticatory and oral musculature. She rapidly opened and closed her mouth several times per second and had bitten her tongue frequently during the previous week. These new movements had obliterated the more typical perioral and lingual movements of tardive dyskinesia described previously. The choreoathetoid movements of her extremities had disappeared. Both authors concurred on a diagnosis of the rabbit syndrome. Benztropine mesylate, 2 mg I.V., did not affect these new movements but brought out the choreoathetoid movements of her extremities. Because of her previous response to oral benzetropine mesylate she was restarted on the drug at a dose of 2 mg b.i.d. A week later, rabbit syndrome symptoms were not present, but symptoms of tardive dyskinesia were again exacerbated.

**0=absent, 1=equivocal, 2=mild, 3=moderate, 4=severe.
***When the rabbit syndrome was present, it was impossible to accurately assess dyskinetic movements of the patient's mouth and jaw.

Discussion

The response of our patient to benztropine mesylate (suppression of the rabbit-like oral movements with a concomitant exacerbation of the dyskinetic symptoms) further demonstrates the clinical independence of these two neuroleptic side effects. To our knowledge, this is the first report describing the effects of an antiparkinsonian drug in a patient simultaneously afflicted with both these drug-induced extrapyramidal syndromes. Although the effects of benztropine mesylate on the rabbit syndrome have been described by Villeneuve (1) and systematically examined by Jus and associates (2), they did not administer this drug to a patient who had both syndromes at the same time. The fact that our patient's rabbit syndrome symptoms were not suppressed by intravenous benztropine mesylate may indicate the dose was too small.

The rabbit syndrome is generally considered to be a form of drug-induced parkinsonism (1, 4), but it is in many ways atypical for this side effect. To date, it has only been reported to develop in middle-aged or elderly individuals (many having evidence of brain damage) who have received neuroleptic drugs for several years (1). We theorize that even though drug-induced parkinsonism and the rabbit syndrome are both mediated by a neuroleptic blockade of the same pool of dopaminergic neurons within the extrapyramidal system, the rabbit syndrome results only when this neuronal pool undergoes structural alteration, possibly by a toxic effect of long-term neuroleptic drug therapy. This pool of neurons (or receptors) appears to be different from the one mediating tardive dyskinesia since both the rabbit syndrome and drug-induced parkinsonism can coexist with tardive dyskinesia yet respond differently to anticholinergic agents (5). Such a hypothesis has already been put forward by Klawans (6) and Cools and Van Rossum (7).

Amitriptyline Therapy in Anorexia Nervosa

BY DANIEL C. MOORE, M.D.

Patients with anorexia nervosa report that they are hungry but use all sorts of techniques, including food refusal, laxatives, and self-induced vomiting, in their pursuit of thinness. The following is a report of the effect of amitriptyline, commonly known to induce weight gain in depressives, in a patient with anorexia nervosa.

Case Report

A thin, attractive 20-year-old college senior first presented with a chief complaint of multiple daily eating and vomiting episodes, which interfered so much with her studies that she chose to drop out of school in December. A thorough medical evaluation failed to reveal any cause for her unusual behavior. Since the patient had been on birth control pills, it was not possible to document amenorrhea.

She described a pattern of going from store to store eating doughnuts, ice cream, pizza, chocolate, and fruit in rapid succession until she felt thoroughly and uncomfortably stuffed, then finding a quiet secluded place to vomit.

Her relentless preoccupation with thinness—which continued unabated even after her weight had gone down to an extremely slender but not emaciated 47.7 kg—began in her sophomore year of college after she met her first real boyfriend, a graduate student. At that time, she was "chubby," having weighed 63.6 kg during and since high school. Her height was 160 cm. They began to date steadily and he exhorted her to lose weight, telling her she was sexually unattractive and "flabby." Soon her failure at dieting joined dissatisfaction with her grades and choice of major as significant frustrations.

It was at this point of extremely low self-esteem and sense of failure that she hit upon the stratagem of vomiting as a way of satisfying both her desire to eat and her pursuit of thinness.

History. The patient's father is a blue-collar worker; her mother has a college education. Her mother has always been overweight and dresses in unflattering clothes.

The pregnancy was marked by bleeding in the third month, and the obstetrician told the mother that the baby would be defective. The delivery was uneventful, but according to the patient, "my mother's milk was bad" and she lost weight from 3.1 kg to 1.36 kg at the end of 2 weeks. She said, "I threw up everything and was crying and crying for 2 weeks. Finally my grandfather recommended goat's milk and I put on weight rapidly and was a chubby baby and have been chubby ever since."

Her mother prepared her for menstruation, and she had an uneventful menarche at age 11 with regular cycles thereafter.

Course of treatment. A sleep EEG ordered to rule out seizure disorder as a cause of the bulimia was negative. Nevertheless, the patient was given a trial of diphenylhydantoin, 100 mg t.i.d., with blood levels of 20 μg/ml. The 2-month trial had no effect on her vomiting pattern. In her psychotherapy the focus was her pervasive sense of ineffectiveness and low self-esteem, reinforcing her awareness of her own wants and needs. A 3-month trial of imipramine, 150 mg/day, had no effect on these symptoms.

Amitriptyline was started 18 months after the patient entered treatment and 2½ years after she began the vomiting, first at 50 mg and later at 100 mg. After the first week, she reported that she felt different and had vomited only twice during the week. During the second week, when the dosage was increased to 150 mg, she felt no desire to vomit but was somewhat anxious because she seemed to be increasing her caloric intake and might be gaining weight.

During the next four months, she vomited a total of four times. Each episode seemed stress-related, was not accompanied by binge eating, and was experienced as ego-alien.

By the end of 4 months on amitriptyline, she had gained 5.0 kg and weighed 52.2 kg, a normal weight for her height. At this point, we tapered her medication over 2 weeks. The day after amitriptyline was stopped, she had a protracted episode of bulimia and vomiting, followed by a week of what sounded like an exaggerated tricyclic withdrawal—malaise, abdominal pains, and nausea. At the end of the second week, she became preoccupied with food, calories, eating, and vomiting to the exclusion of the other therapeutic issues on which she had worked so well for the past 4 months. The next week, she called in tears to say that she had been eating and vomiting continually and would like to resume the amitriptyline. The bulimia stopped within 2 days and her preoccupation with weight became a background issue once again. Psychotherapy continues on issues of personal effectiveness and awareness of wants and needs.

Discussion

This case satisfies the Feighner and associates (1) criteria for anorexia nervosa, although Bruch (2) would probably label it atypical anorexia nervosa because of the prominence of bulimia and vomiting and compulsive rituals about eating. The resemblance of these symptoms to those described by Rau and Green (3)

Dr. Moore is Instructor of Psychiatry, Department of Psychiatry and Connecticut Mental Health Center, Yale University School of Medicine, 34 Park St., New Haven, Conn. 06508.

as being responsive to anticonvulsants prompted the unsuccessful trial of diphenylhydantoin.

Tricyclic antidepressants were specifically chosen because of their success in some cases of obsessive-compulsive neurosis (4), which anorexic eating behavior sometimes resembles. Needleman and Waber (5) have also used amitriptyline recently in six cases of anorexia nervosa, but their original purpose was to treat the motor retardation and sadness observed. They reported weight gain and normalization of mood.

The lack of effectiveness of imipramine in this case compared with amitriptyline suggests an interesting line of speculation about the mechanism of action. Animal studies by Carlsson and associates (6) on the ability of various antidepressant drugs to prevent depletion of intraneuronal 5-hydroxytryptamine (5-HT) stores caused by 4-methyl-α-ethyl-metatyramine show that the order of potency in preventing 5-HT depletion is chlorimipramine followed by amitriptyline, imipramine, chlordesipramine, nortriptyline, and desipramine. Sheard and associates (7) have shown a similar order of potency in depressing the firing rate of the midbrain raphe, presumably because decreased reuptake causes increased 5-HT availability at the receptor and feedback inhibition of presynaptic neuronal activity. This suggests that amitriptyline is more potent than imipramine in blockading reuptake of 5-HT, and Maas (8) has suggested that the difference may be even larger in therapeutic situations, since amitriptyline is rather slowly broken down to its metabolite nortriptyline while imipramine is rapidly metabolized to desipramine.

Studies have suggested that plasma-free tryptophan is a determinant of brain tryptophan levels (9). Because brain tryptophan concentration is known to be an important factor influencing brain serotonin levels, Coppen and associates (9, 10) have used free plasma tryptophan levels to study patients with depression and patients with anorexia nervosa. Free plasma tryptophan is significantly low in both conditions but returns to control levels in recovered depressives, while remaining low in anorexics after they have returned to near normal weight on a psychiatric ward. The failure of low plasma tryptophan, unusual eating habits, and amenorrhea to return to normal suggests that induced weight gain alone does not attack the basic causes of anorexia nervosa and therefore leaves the patient at risk for frequent relapses.

The success with amitriptyline in this case and the six others reported by Needleman and Waber (5) suggests that drugs which prevent reuptake of 5-HT and decrease its turnover in the brain may be useful in anorexia nervosa. Since chlorimipramine is the most potent of these drugs, it probably deserves a trial in this condition.

Nuclear Symptoms of Schizophrenia After Cingulotomy: A Case Report

BY JAVIER I. ESCOBAR, M.D., AND VIJAYA CHANDEL, M.D.

The importance of the limbic system in the genesis of schizophrenic symptoms has been highlighted in recent reviews (1, 2). Schizophrenia-like symptoms are reported to occur frequently in temporal lobe epilepsy and other instances of "injury" to limbic structures, e.g., some brain tumors (3).

We wish to describe an illustrative case in which "nuclear" symptoms of schizophrenia (4) first developed after a cingulotomy. The exacerbation and diminution of these symptoms during treatment with imipramine, methylphenidate, and neuroleptics are described. We theorize that schizophrenia-like symptoms may have resulted from the lesion to the cingulum and that

Dr. Escobar is Associate Professor of Psychiatry and Dr. Chandel is Resident in Psychiatry, University of Tennessee at Memphis School of Medicine. Address reprint requests to Dr. Escobar at the Memphis Mental Health Institute, 865 Poplar Ave., Memphis, Tenn. 38105.

fluctuations in symptoms during pharmacotherapy were mediated through changes in catecholamine turnover (primarily dopamine) in the mesolimbic system.

Case Report

The patient, a 44-year-old married woman, was referred to the Memphis Mental Health Institute in January 1977 because of "intractable depression" 7 months after a cingulotomy.

Symptoms of depression were first noticed in 1974 and worsened over the next year. In 1975 the patient took an overdose of diazepam. She was hospitalized five times the following year with a diagnosis of "involutional melancholia." She received tricyclic antidepressants at first, but because of "lack of response to drugs" she was given ECT on four different occasions. Response to each course of ECT was transient, and by mid-1976 the patient's situation had become desperate. Her depression was extremely severe and refractory to traditional treatments.

A bilateral cingulotomy was performed in June 1976 in a private hospital. Following an uneventful operation, her symptoms of depression were unchanged, and she developed additional symptoms with a nonaffective quality—nihilistic and somatic delusions, feelings of depersonalization and derealization, and paranoid ideas. According to family interviews and past hospital records, such symptoms had not been present before the surgery.

The patient's medical history included a hysterectomy in 1970 and removal of an ovarian cyst in 1972. Following the 1972 surgery, she developed "gastrointestinal complaints and nervousness" for which diazepam was prescribed. The history is otherwise unremarkable. Family history revealed the presence of depression in the patient's mother and her older sister.

On admission to the institute the patient exhibited affective blunting, anhedonia, nihilistic and somatic delusions, feelings of depersonalization and derealization, and Schneiderian symptoms of schizophrenia (delusions of influence, auditory hallucinations, and thought broadcasting). No evidence of organicity was found. Physical and laboratory findings were unremarkable other than an EEG that showed "mildly irregular and slow diffuse activity; findings indicative of mild underlying cerebral dysfunction." A sleep-deprived EEG did not show any changes over the baseline EEG. A neurological consultation revealed no gross abnormality, and neuropsychological test results gave no evidence of lateralizing dysfunction or deterioration of brain function compared with the precingulotomy test results. The brain scan was normal. After her admission to the hospital, there was a 7-day medication wash-out period for baseline observation, during which time the symptoms of psychosis were unchanged. Therapy with imipramine and methylphenidate was initiated, with maximum daily dosages of 300 mg of imipramine and 30 mg of methylphenidate attained by the second week of treatment. On this combination therapy, her insomnia disappeared and there was a remarkable increase in psychomotor activity. However, bizarre ideation became evident and the patient began to experience cenesthesic hallucinations (i.e., she felt the floor moving under her feet and her body being pulled in different directions). There was also a net increase in auditory hallucinations and she constantly heard "voices and noises." No signs of organic brain syndrome were found at any time.

Because of this exacerbation in her symptoms, methylphenidate was discontinued and a neuroleptic agent, trifluoperazine, was added to the treatment at dosages increasing to 60 mg/day, at which point imipramine was discontinued. With neuroleptic therapy, the patient showed rapid and dramatic improvement, and by 3 weeks later the psychosis had totally faded. Affective blunting and anhedonia were the only remaining symptoms. The patient was able to leave the hospital to be followed on an outpatient basis, and her clinical improvement has been maintained at 2-month follow-up.

Discussion

A connection between lesions of the limbic system and schizophrenic symptoms is supported by the following facts (2).

1. Ablation of limbic structures in animals produces profound changes in affect and emotion, and an impairment in the capacity to "filter out" stimuli (these are thought to be basic disturbances in schizophrenia).
2. Experimental stimulation of the limbic system in humans produces perceptual distortion and feelings of depersonalization.
3. Temporal lobe epilepsy (which commonly involves limbic structures) closely resembles schizophrenia.
4. Encephalitis, a disease that frequently affects the temporal lobes and the basal ganglia, gives rise to schizophrenia-like symptoms.

The dopamine hypothesis, a leading theory in attempts to understand the pathophysiology of schizophrenia, is based on differential effects of dopamine agonists and dopamine blockers on symptoms of schizophrenia. Dopamine agonists such as L-dopa, apomorphine, amphetamines, and methylphenidate produce schizophrenia-like symptoms, while dopamine blockers such as neuroleptics decrease symptoms (1).

Of the dopamine pathways, the mesolimbic dopamine system that connects limbic structures (olfactory tubercle, nucleus accumbens, and stria terminalis) to the midbrain has been called the "seat of schizophrenia" (5). This is also thought to be the relevant tract for amphetamine psychosis, a model psychosis mediated by catecholamines (6). The area of the cingulum is an important part of the limbic system. Tumors involving the cingulate gyrus have been shown to produce florid symptoms of schizophrenia in humans (3). Stimulation of the cingulum produces catatonia-like states in animals (2). Furthermore, frontal lobe lesions

are known to produce schizophrenia-like symptoms, particularly if they involve the cingulum (2).

Psychosurgery causes specific lesions to limbic structures. A cingulotomy involves destruction of white matter with its cingulate fibers above the corpus callosum and approximately 3 cm posterior to the tip of the frontal horn of the cerebral ventricles. Although the "target" lesion encroaches on area 24, adjacent areas of the corpus callosum and calloso marginal gyrus may also be damaged (7). The cingulate gyrus, with its connections to the temporal lobes, the hypothalamus, and other limbic structures, is thought to be a crucial area in controlling emotional and autonomic responses. Cingulotomy is reported to produce beneficial effects in obsessive-compulsive neurosis and depressive disease, but it is thought to be ineffective in schizophrenia (7).

In the case we have presented, a cingulotomy performed to treat a chronic depressive disorder activated schizophrenia-like symptoms. This emergence of symptoms following a cingulotomy is consonant with reports describing schizophrenia-like symptoms in association with different limbic lesions. The worsening of symptoms with methylphenidate administration and their reversal by a neuroleptic drug is of particular clinical interest and suggests the possibility that the symptoms were mediated through catecholamines, mainly dopamine, in the mesolimbic system.

To our knowledge, this is one of the first reports of schizophrenia-like symptoms as a complication of psychosurgery. However, since our observations were primarily retrospective, we cannot rule out the possibility of an insidious schizophrenic syndrome that could have been activated by the surgical procedure.

The Difficult Defendant: A Case Report

BY HAROLD C. MORGAN, M.D.

Although problems with the behavior of defendants in the courtroom seem to have been increasing during recent years, there has been very little psychiatric literature about this problem.[1] It is my impression that the obstreperous defendant who disturbs, frustrates, and puzzles the court is no longer uncommon. This problem may be manifested in strange or disruptive behavior or threats to the judge, the jury, or to the self. What problems does this present for the psychiatrist who has the responsibility of evaluating the defendant and advising the court? What are his responsibilities to the defendant and to the court? How does he reassure the judge in the face of the defendant's threats of homicide or suicide? How does he reconcile potential conflict of interest between responsibility to the court and responsibility to the defendant? How does the psychiatrist tread the narrow path of neutrality? How does he deal with his own apprehensions?

Answers to these questions do not come easily and there are no absolute standards that can be applied universally, but we can gain some answers from clinical experience with individual cases. One particularly difficult case in my experience recently provided some insights and ideas for resolving these problems.

Case Report

The defendant was on trial for one of several major crimes with which he had been charged. While serving time in prison for another offense, he had been attacked. He was transferred to the state maximum security prison-hospital for his protection and for treatment of emotional problems and was transported daily to court.

During jury selection the defendant, looking dapper and distinguished, "aided" his counsel in the selection process. Soon after the trial was underway, the defendant was described by court personnel as "emotionally upset"; he talked of suicide and switched to prison clothes. I was called to examine the defendant for competency to stand trial.

When this paper was written, Dr. Morgan was Fellow in Forensic Psychiatry, Institute for Law and Psychiatry, McLean Hospital, Belmont, Mass. He is now in private practice at P.O. Box 11098, Capitol Station, Columbia, S.C. 29211.

[1]A computer search of *Index Medicus* and *Psychological Abstracts* for the past seven years revealed no truly pertinent journal articles.

Before the competency examination a conference was held in the judge's chambers in which counsel for the prosecution and the defense, law enforcement officers, and security personnel were informed of the legal delicacy of the situation and the importance of avoiding a mistrial. The examination itself was conducted with the defendant's attorney and a security guard present. I found the defendant to be angry, scared, and tearful, but competent. The judge and all counsel were informed of these findings and I then informed the defendant personally of my conclusions.

The trial continued with periodic interruptions by the defendant, who threatened suicide and dire harm to others, including his court-appointed attorney and the transporting officers. From time to time, I was called on to assess and assuage the defendant's perturbations and to deal with the apprehensions of all those in court. For the first task, interviews were held with the defendant in the holding room adjacent to the courtroom with security officers stationed nearby. Although it was observed, the conversation was essentially private. He talked freely while I listened and commented supportively. For the second task, group conferences were held in the judge's chambers during which I reported my findings and made suggestions. There was opportunity for questions and answers about the defendant's behavior and the risk of harm to others. This group ventilation afforded a means of relieving anxiety surrounding these risks and fears and drained away part of the hostility that was being focused on the defendant.

Discussion

This two-fold approach to the problem, in which both the defendant's emotions and those of court personnel were examined, served to interrupt the cyclical pattern of acting-out by the defendant and retaliative measures by the court. The bilateral hostility of the opposing camps was relieved and the defendant and his keepers developed more mutually tolerant attitudes. Equally important, the trial was continued to satisfactory completion.[2]

Thus far, I have mentioned only the clinical-administrative difficulties; nothing has been said of my feelings, apprehensions, or misgivings as the psychiatric consultant in this situation. Does the consultant feel in danger when he interviews such a difficult defendant in private? Do the defendant's threats toward others inspire fear that he will similarly threaten—or harm—the psychiatrist? Unequivocally, the answer is yes. Any psychiatrist who denies concern about this risk probably does not understand the situation. The psychiatrist's own apprehensions may prejudice him against the defendant. The consultant must recognize this bias as it arises and try to resolve it immediately in order to have an open mind about the defendant, who will recognize and exploit anything less.

One effective way to resolve this conflict is to recognize the defendant's feelings and to explain clearly the difficult responsibility the psychiatrist has, i.e., being fair and honest with both the defendant and with the court. An understanding of the defendant's legal situation and his emotional reaction to that situation should also be expressed. In short, total fairness and honesty with the defendant is the best protection against threat or assault. It is also the best approach to the sensitive issue of professional loyalties and responsibilities and the best way to remain neutral. As is the case with any potentially dangerous, threatening person, it is wise to have one or more security officers nearby. (I have been assaulted by psychotic offenders, but I have never been attacked or even threatened by a nonpsychotic one.)

In summary, the difficult defendant arouses anxiety and sometimes anger in everyone in the courtroom, from the highest judge to the lowest clerk. The psychiatric consultant to the court is primarily responsible for determining the defendant's clinical state, but he should be aware of the feelings and needs of others in the courtroom. Ideally, the psychiatrist becomes an intermediary. Informing the court of the defendant's feelings along with suggestions for responding to the defendant will usually lead to better understanding of the defendant and diminished apprehension, which will contribute to more suitable behavior by the defendant. It is imperative that the consultant be completely fair and honest in dealing with the defendant. If he is not, the consultant will be professionally ineffective and personally uncomfortable. An honest, unbiased approach of open communication with all concerned generally leads to conformity by the defendant, relief of the court's anxiety and, in the case I have reported, gratitude from both.

[2]After the trial was over, I received handwritten notes of appreciation from both the judge and the defendant.

Transcendental Meditation as an Alternative to Heroin Abuse in Servicemen

BY DOUGLAS J. ANDERSON, MAJ., MC, USAR

Several impressive retrospective studies demonstrate that many former drug abusers who regularly practice Transcendental Meditation (TM)[1] have abandoned their use of marijuana, LSD, amphetamines, barbiturates, narcotics, alcohol, and even tobacco (1–4). This finding suggests that drug abuse might be significantly reduced if abusers could be taught to practice TM as an alternative. I investigated TM as an alternative to drug abuse in young servicemen who had been identified as heroin users. The purpose of this study was to determine whether such a population could be motivated to continue practicing TM and, if so, whether there would be a decrease in drug abuse.

Unpublished prospective studies by Brautigam in Sweden (cited in reference 5) and by G.E. Schwartz in the United States supported this hypothesis by showing a significant decrease in drug abuse in small populations of drug abusers who were taught to practice TM. However, these investigations were biased because the populations studied were particularly interested in learning TM or were novice meditators already. The retrospective studies were also biased in that most of the subjects were highly motivated college students who were well-established in the practice of TM. A more recent unpublished study by Benson and associates (cited in reference 6) of the usefulness of TM in a population of 4,000 high school students showed an insignificant decrease in drug abuse among meditators as compared with controls; in fact, only 1.3% of the subjects could even be persuaded to use meditation regularly. They concluded that TM was not acceptable to high school age populations as an alternative to drug abuse but indicated that the study did not refute the potential usefulness of TM in the treatment of drug abuse in other populations.

It became clear to me that when individuals were motivated to practice TM, a decrease in drug abuse could be expected. The problem was finding out who could be motivated to learn the technique. I therefore decided to determine whether TM might be useful in the treatment of heroin use in young servicemen.

Method

A population of 115 admitted heroin users was studied. The subjects included a few soldiers who volunteered for detoxification, but most were either brought in under the influence of heroin (confirmed by urine drug screen) or were referred for detoxification after a positive result on a random urinalysis ordered by the subject's unit. The subjects ranged in age from 19 to 26 years, with a mean age of 20. Most were weekend users of heroin, and none was physiologically addicted at the time of admission. Detoxification was done on a locked ward, and, although the subjects were given no medication, withdrawal symptoms (if any) were extremely mild. The subjects remained on the ward for 5–7 days. After detoxification, 89 subjects were returned to duty; 26 subjects were in the process of being separated from the service for repeated drug abuse and were evacuated to military hospitals in the United States for final discharge.

All individuals admitted to the hospital for heroin detoxification during the study period volunteered, willingly and with informed consent, to participate in the study. Each subject was taught to practice TM for 15–20 minutes twice each day by a qualified instructor from the Ananda Marga Yoga Society of Berlin.[2] The subjects were also urged to attend Yoga society meetings after discharge. Follow-up was arranged in two ways. The subjects who returned to duty were referred to the Community Drug and Alcohol Assistance Center (CDAAC) for mandatory counseling. All subjects gave permission for confidential consultation with CDAAC counselors who provided follow-up information. The subjects who were in the process of being discharged from the service were given a questionnaire to complete 1 month after returning to civilian life. Basically, they were asked whether they were still meditating and whether they were again using heroin or other drugs.

Results

All of the subjects were enthusiastic about learning TM from their instructor and practiced diligently in the hospital. However, of the 89 subjects who returned to duty, none reported continuing TM after leaving the hospital. Moreover, all returned to some form of drug abuse almost immediately, although most were using drugs other than heroin. Of the 26 subjects who returned to civilian life, only 2 returned their questionnaires. These 2 subjects, who represent 1.7% of the total sample, indicated that they were continuing to meditate and to refrain from drug use. They also were continuing to maintain postal contact with the Ananda Marga Yoga Society after the conclusion of the study.

When this work was done, Dr. Anderson was Chief, Department of Psychiatry, U.S. Army Hospital, West Berlin. He is now Staff Psychiatrist, Long Beach Veterans Administration Hospital, Long Beach, Calif. 90822, and Clinical Instructor in Psychiatry and Human Behavior, University of California, Irvine.

The author wishes to thank Tattvika Amshumalii Brahmacarii of the Ananda Marga Yoga Society of Berlin who served as the meditation instructor for this study.

[1]Transcendental Meditation and TM are trademarks of the World Plan Executive Council-United States.

[2]Although the trademarked term "TM" is used throughout this paper, the Ananda Marga Yoga Society of Berlin is not affiliated with any organization in the United States.

Discussion

The subjects' enthusiasm for learning TM probably resulted from the welcome visits by a nonmilitary instructor who helped to relieve the boredom of confinement. TM was readily practiced by all of the subjects while they were in an environment that provided little else to do. The practice of TM was reinforced in the hospital by regular instruction and peer identification, but after discharge the subjects were on their own. Although additional instruction was available through the Yoga society, none of the subjects made use of it. Therefore, the exposure to TM was unfortunately brief, and this may be one reason for the negative results. Candelent and Candelent (7) have noted that the effects of TM are gradual and usually are not noticeable until after several weeks of regular practice.

The results are interesting and support Benson and associates' conclusion that TM is not an alternative to drug abuse for all populations. TM seems to be of benefit only to those who have the motivation to continue to practice it regularly. If this is true, TM may be no better than any alternative that requires motivation (e.g., a hobby or a sport). Another factor that may have influenced the results is the possibility that this group of young men have not yet completed adolescence and have a need to test limits and challenge authority that might make drug abuse more appealing than any legal alternative.

In conclusion, it seems that TM cannot be offered to any group of drug abusers with the expectation that they will turn away from their drugs and embrace meditation. Further study is needed to determine what differentiates the drug abuser who develops motivation for an alternative from the one who does not.

Can Dialysis Help the Chronic Schizophrenic?

SIR: The fascinating Clinical and Research Report on "The Use of Hemodialysis in Chronic Schizophrenia," by Herbert Wagemaker, Jr., M.D., and Robert Cade, M.D., (June 1977 issue) prompts me to recount my experience with hemodialysis used to treat a patient with chronic paranoid schizophrenia.

The patient, a 35-year-old single unemployed man, first manifested schizophrenic symptoms at age 21. He had multiple psychiatric hospitalizations in private and state psychiatric facilities, where the diagnosis and illness course were well-documented. While he was an outpatient, the patient developed a water-drinking compulsion-delusion that led to water intoxication and had a major motor seizure with rhabdomyolysis. He then developed acute tubular necrosis and renal failure. The patient had 24 hemodialysis treatments over 8 weeks, with complete return of renal function.

As a psychiatric consultant to the medical ward, I had the opportunity to follow this patient almost daily during and after the dialysis. Although haloperidol, 80–100 mg/day, did decrease his agitation, the patient's psychotic symptoms remained essentially unchanged, with persistent flat affect, looseness of associations, hallucinations, delusions, and suspiciousness throughout the hospitalization. Upon his return to the psychiatric hospital following the completion of dialysis, nursing staff members who were familiar with the patient from previous hospitalizations noted no significant changes in his behavior, symptoms, or hospital course. He did improve enough to be discharged after 7 weeks.

Dialysis did not alter this patient's schizophrenic symptomatology, although it certainly proved useful for his acute renal failure. It seems that he would fall in the "dialysis nonresponsive" category in contrast with most of the "dialysis responsive" patients reported by Drs. Wagemaker and Cade.

I hope that others who have had clinical experience with schizophrenic patients on hemodialysis will report them in order to expand the groups of responders and nonresponders. Carefully controlled double-blind studies are needed to better examine this potentially productive area.

WILLIAM W. WEDDINGTON, JR., M.D.
Durham, N.C.

SIR: I found the article by Drs. Wagemaker and Cade intensely interesting. I would like to detail a professional experience that the authors and *Journal* readers may find provocative. From 1968 to 1973 I was an assistant professor of psychiatry and served as liaison psychiatrist to an organ transplant-hemodialysis unit. I routinely interviewed all patients, both old and new, as well as treating psychiatric complications of all types.

Of relevance to the article by Drs. Wagemaker and Cade was a young man who at 17 had both kidneys removed secondary to nonfunction and blood pressure complications due to glomerulonephritis. A transplant kidney from a related donor did well for about 5 months but was then rejected and removed. Repeated cadaver transplants all failed. When I first saw him, he was receiving hemodialysis every 3 days and had no functioning renal tissue at all. However, he was doing well otherwise. Evaluation showed him to be a reasonably adjusted schizoid personality. Some months later, still on hemodialysis, he suffered an acute paranoid schizophrenic decompensation, his symptoms having gone unnoticed by the staff for about 2 weeks.

Administration of phenothiazines, notably moderate doses of trifluoperazine and chlorpromazine, quickly controlled the acute symptoms. These medications were necessary for 2½ years, after which the patient entered a good remission and psychotropic drugs were discontinued. He remained in good mental health until his death from water intoxication and the complications of long-term hemodialysis about a year later.

During the entire period of his schizophrenic illness, this patient received hemodialysis every 3 days, and no variation in mental status related to dialysis was noted. A change to a more efficient dialysis machine also produced no differences. His remission occurred shortly after he had been dropped as a possible transplant recipient and placed on less frequent and less thorough maintenance dialysis. His mental condition varied, but it did so in relation to the state of renal function, as detailed in a paper by Ferris (1). The role of continuing total absence of functional renal tissue compared with the status of Wagemaker and Cade's patients, who had normal renal function, is a matter for speculation.

If their results can be replicated, I believe the authors have produced a landmark paper. The dialysate content in particular may lead to a major biochemical breakthrough in the understanding of a stubborn and mysterious illness.

GILBERT N. FERRIS, M.D.
Richmond, Va.

SIR: The interesting article by Drs. Wagemaker and Cade in the June 1977 issue necessitates some comment. It would be most fortunate if the conclusion that "some chronic schizophrenics are helped by dialysis" stated in this article were true. However, based on physiological reasons and the clinical experience I have accumulated in 13 years of studying these patients, I must express some serious doubts about the possibility of that conclusion being verified.

As to the physiology of kidney function, the ability of hemodialysis to remove both foreign chemicals and normal metabolites is far inferior to that of normal kidneys. Since schizophrenics have normal kidney function, why should their kidneys be less able to remove the hypothetical foreign chemical in their blood in a system superior to man's makeshift artificial kidney machine? As to clinical experience in this area, Reichsman and I intensively studied a group of hemodialysis patients over a period of 4 years at the State University of New York Downstate Medical Center (1). Two patients who were schizophrenic prior to being on dialysis continued to have this illness after they started dialysis and throughout the years of their treatment. In another study that Wynbrandt and I conducted (2), one patient in our series who was schizophrenic prior to the onset of kidney disease was not helped psychologically by dialysis and as a result of the stresses of this procedure had a most arduous course that led to her death.

I have been active in research in this area and have reviewed the literature rather extensively (3). I know of no report of improvement in the psychological state of schizophrenic dialysis patients maintained by this procedure. Of course, this may be due to my failure or the failure of other investigators to make accurate observations. However, another possibility is that the effects Drs. Wagemaker and Cade have reported are either happenstance or a placebo effect of this procedure. I hope that I am wrong.

NORMAN B. LEVY, M.D.
Brooklyn, N.Y.

Dr. Wagemaker Replies

SIR: We think the substance being removed from the patient's bloodstream is a polypeptide, which probably would not be removed by the kidney. The artificial kidney filters out anything that will pass through the filter.

Dr. Levy mentions three cases of schizophrenics who did not respond to dialysis with psychological improvement. We never claimed that all schizophrenics would respond; in fact, it would seem improbable that all would. Furthermore, the complications of renal failure certainly alter the biochemistry of the body to such an extent that it would be hard to separate out cause and effect.

The placebo effect of dialysis certainly needs to be reckoned with. However, I would not expect this effect to last four years in one case and more than two years in another. We are planning to carry out a double-blind sham dialysis experiment to evaluate this.

Our patients who have responded to dialysis are able to live lives of quality. Many of them are back at work or in school, and they are able to socialize and enter once more into meaningful relationships. Our experiments are preliminary, but we have been greatly encouraged by the improvement in quality of life of our patients following dialysis.

HERBERT WAGEMAKER, M.D.
Louisville, Ky.

Availability of L-Tryptophan

SIR: American psychiatrists must now face another pharmacotherapeutic dilemma. Ernest Hartmann, M.D., in his article "L-Tryptophan: A Rational Hypnotic with Clinical Potential" (April 1977 issue) gives us a very nice summary of already completed research, and it certainly appears that L-tryptophan should have a place in our formularies. We all know, however, that in the United States a physician cannot prescribe L-tryptophan as of this writing. It should be pointed out, however, that L-tryptophan can be purchased at "health food" stores for about 25¢ per 500 mg. It is not clear how a substance can be approved as a "food" and not as a pharmaceutical agent.

Pending approval of L-tryptophan for marketing by the pharmaceutical industry, I would like to ask the following: what are the legal and ethical ramifications if a physician "prescribes" L-tryptophan by advising his/her patient to buy it at the local health food store?

R. HARLAN BRIDENBAUGH, M.D.
JOHN G. LAFFT, M.D.
Washington, D.C.

Dr. Hartmann Replies

SIR: I agree with Drs. Bridenbaugh and Lafft that a dilemma exists: L-tryptophan is readily available as "food" and, in fact, appears on the Food and Drug Administration's (FDA) list of food substances generally recommended as safe. At the same time, it is not available as a drug in the United States, and I have had to conduct many studies under procedures for the investigation of a new drug as if L-tryptophan were a newly synthesized molecule.

I can think of no totally logical reason for the approval of a substance as a food but not as a drug. However, I am sure the FDA can think of some legal reasons. In fact, I have sent a copy of Dr. Bridenbaugh's letter to the FDA, and if I receive an answer I will be happy to share it with him and with the readers of the *Journal*.

To have L-tryptophan approved as a drug would require someone (presumably a pharmaceutical company) to spend a million dollars or more on studies to demonstrate the safety and efficacy of a substance that would then not be patentable. I very much hope a company will accept the challenge and that the FDA will be somewhat accommodating, since the efficacy of L-tryptophan in reducing sleep latency is fairly well established, and widespread clinical experience with its use as an antidepressant should at least partially fulfill the safety requirements. Some studies, including those involving

long-term administration or administration to pregnant animals, will certainly still be required.

In regard to Dr. Bridenbaugh's final question, I do not presently see any ethical problems in advising a patient to obtain L-tryptophan at a health food store. Assuming that the doctor is convinced that there are not contraindications to the use of L-tryptophan, advising the patient to buy it would be similar to advising him to buy vitamins or to obtain a dietary supplement of some kind. I do not know of any legal ramifications, but further clarification of this issue may be forthcoming from the FDA.

ERNEST HARTMANN, M.D.
Boston, Mass.

Editor's Note. Since Dr. Hartmann wrote his response to Drs. Bridenbaugh and Lafft, he has notified us that he received a communication from Stephen McNamara, Associate Chief Counsel for Food of the Food and Drug Administration, portions of which follow.

> Pursuant to the Federal Food, Drug, and Cosmetic Act, (21 USC 321 (s), 342 (a) (2) (C), and 348) if an ingredient used in a food product is not "generally recognized as safe" under the conditions of its intended use, it is a "food additive" and may not be used without prior FDA approval. FDA has promulgated a food additive regulation approving certain limited uses of L-tryptophan. This regulation, however, does not appear to authorize the sale of L-tryptophan in tablet form as a dietary supplement. If, in fact, the "health food" L-tryptophan products to which you refer are not "generally recognized as safe" or encompassed by the food additive regulation, they are subject to regulatory action under the Federal Food, Drug, and Cosmetic Act.
>
> A physician's action in advising a patient to consume, for therapeutic purposes, an article commonly sold as a food is generally not a subject of regulation by the FDA under the Federal Food, Drug, and Cosmetic Act. FDA has stated that the act does not provide the agency authority "to regulate the practice of medicine as between the physician and the patient." Indeed, pursuant to this premise the courts have ruled that the act does not prohibit a physician from prescribing a drug for a new use which has not been approved by FDA.[1]
>
> Of course, if a physician's advice to his patient is not in accord with sound medical practice, the physician may be subject to action under state law. For example, a physician who acts in a negligent manner may be subject to a civil action for damages or to the loss of his license to practice medicine. However, the prescription of an article which FDA has not approved is not necessarily a negligent act.
>
> Your letter expresses doubt that an article may properly be approved by FDA for use as a food but not as a drug. It appears that this circumstance is both reasonable and consistent with law. Speaking generally, the new drug provisions of the Federal Food, Drug, and Cosmetic Act require that a subject article be shown to be both safe and effective for its intended therapeutic use before a new drug application may be approved by FDA. An article that has been approved for a particular food additive use may nevertheless *not* have been shown to be safe and effective for a distinct therapeutic purpose.

[1] *FTC v. Simeon Management Company*, 391 F Supp 697, 706-707 (ND CAL-1975), affd 532 F 2d 708, 716–717 (9th Cir 1976).

Borderline Versus Narcissism

SIR: With reference to the excellent paper "Borderline Rage and the Therapist's Response" by Theodore Nadelson, M.D. (July 1977 issue), I wish to emphasize a distinction between borderline rage (in patients who were sadistically treated by their parents) and narcissistic rage (in patients who were seductively "too well" taken care of by parents who wanted them as companions to counterbalance their own depression and passivity). The borderline person, as Dr. Nadelson pointed out, has not integrated the hostile and caretaking parts of the parental imagoes and projects these hostile introjects onto others. He then has an active fear of his own destructiveness and a passive fear of annihilation.

The narcissistic patient projects rage, but it is secondary to a particular kind of fear. The threat in the narcissistic personality is abandonment and becoming a totally depleted shell in caring for himself. Both borderline and narcissistic patients have intense hate and self-hate, and both types of people engender in the therapist strong desires to retreat or to become overactive and to allow premature termination. Both types of patients accuse us of being ineffectual or rejecting and of feeling hopeless.

Although the symptoms are similar, narcissistic and borderline pathology are distinct and different. The inner needs and dynamics of borderline and narcissistic patients are different, although they may initially present in the same way. The borderline patient needs to control destructiveness mainly by distancing. The narcissist needs to deny separateness and resists demands for autonomy and for self-care and care for others. The rage and self-denigration of the narcissist cover a profound fear of fusion. He feels good only when he feels totally in control but totally and passively taken care of. Action is an intrusion perceived as "too much hassle," but the narcissist complains of being excluded from all the action. Parents of narcissistic children encourage passivity in their children and tell them they are better than and different from the wild and unruly neighborhood children. These mothers are idolized by the child, but later they incur the child's rage when he discovers the world does not reward passivity. Closeness is mistakenly held to be narcissistic fusion and retreat rather than shared activity. At first these "good children" are adored, but later their passivity is treated with annoyance, condemnation, and disgust by the parents. Once again, active coping is bypassed. Revenge and passive withholding then become the life-style, which causes the self-hate and guilt. Separateness causes pain due to loss of a fused self-object. Often these lonely patients inflict isolation on themselves when disappointed and use this pain as a punishment and precondition for their revenge taking.

When the narcissist accuses us of not helping he is saying that we are demanding active coping which exposes his helplessness and intrudes on the blissfully fused narcissistic activities to which he feels entitled. The rage is particularly painful because it is felt against "good parents." For the narcissist, it is not sufficient to delimit hostility and curb projection. The narcissist needs a steady and consistent confrontation with his passive demands when active decision making, sharing, and coping are in order. The rage of being forced to take care of himself must be converted into the pride of being able to give up passive seductive modes and to feel actively in control, including being able to complete

tasks. Covert parental patterns of passivity set up as ideals must be converted to active participation with other people.

Narcissistic and borderline patients are often confused with one another, especially when rage is the presenting symptom. Since they cause very similar countertransference responses, I think it is worthwhile to emphasize their distinction and their different dynamics. Both sets of patients suffer from a conviction of being "unwanted, unloved, unredeemable, doomed, and guilty." The borderline feels this way because of the splitting or lack of integration of his introjects and the projection of both his good and his hostile parts, while the narcissist feels cheated and rejected because of his neediness, passivity, use of people, and rage when he is called upon to act or give. When our patients occasionally combine both of these character pathologies, it is important to interpret appropriately both contexts, to be effective, and to prevent premature termination of therapy.

HELEN STEIN, M.D.
Fresno, Calif.

The Therapist as Participant-Observer

SIR: I very much enjoyed "Psychiatric Eclecticism: A Cognitive View" by Joel Yager, M.D. (July 1977 issue). It is literate, reasonable, and coincides nicely with my own views. I would like to comment on the concept of the participant-observer Dr. Yager mentioned but did not develop.

In Dr. Yager's Venn diagram, the client is seen as a disease by the medical observer, a mind by the psychological observer, an autonomous machine by the behavioral observer, and a cog in a machine by the social observer. It is the therapist as participant-observer who sees the client not as an object but as a person who talks to him and develops the relationship that makes all the rest work. The domain of this observer is the center area of the diagram intersected by all the others. It is from only this position that the therapist can have immediate access to each of the other vantage points, singly or in groups of two or three.

Each of Dr. Yager's four observers plays a fixed role in therapeutic relationships. The medical observer's role is a god and the psychological observer's a father (analysts), mother (social workers), or friend (Rogerians), depending on the therapist's own parataxic distortions. The behavioral observer's role is like an automobile mechanic and the social observer's like a politician.

The participant-observer must be able to use as many roles as possible in order to develop a relationship custom-made for each client. To approach a sociopath in the same way that one would approach a compulsive neurotic or a schizophrenic seems to me to be courting disaster. Nor can one approach two compulsive neurotics in exactly the same way—they are different people and require different relationships.

The exposition of role choices by the participant-observer requires a Venn diagram that I am not yet old enough to draw.

Seattle, Wash.

A Neglected Reference

SIR: One of the reasons stated by Nancy C. Andreasen, M.D., and Janusz Bardach, M.D., for presenting "Dysmorphophobia: Symptom or Disease?" (June 1977 issue) was that "A search for references to this term in English yielded only one citation, a definition in a psychiatric dictionary." Hay's overview and report on 17 cases, including 8 case histories (1), was overlooked by the authors and by the reviewer.

This is not to say that Hay's paper gives a sense of closure about dysmorphophobia, which was found to be a nonspecific symptom. However, the picture presented by Hay differed somewhat from that of Drs. Andreasen and Bardach. In short, "Using [Kurt Schneider's] conceptual framework, 11 of the 17 patients were thought to be suffering from severe personality disorder, 5 were schizophrenic, and one had a depressive illness."

The only case that I have treated was a young woman who had an elaborate paranoid delusional system in addition to her continuing concern with the shape of her attractive nose, for which she had had several operations.

KENNETH NAKDIMEN, M.D.
New York, N.Y.

Dr. Andreasen Replies

SIR: My first reaction on learning of Hay's article was chagrin. When conducting our literature search Dr. Bardach and I were surprised to find so little in English, but how could we have missed an article actually titled "Dysmorphophobia" and published in a major journal? I hastened to the library and consulted *Index Medicus* again—first under "dysmorphophobia," then "self-concept," "cosmetic surgery," "plastic surgery," "delusions," etc. Looking under Hay's name to be sure the article was listed in some way for 1970, I found the reference. But how was the subject indexed? As a shot in the dark, I looked under "phobia," and there it was.

I have heard people object to the term "dysmorphophobia" because the disorder is not a phobia, but I have replied that no one takes the term literally. Now I know that indexers do. On the positive side, I also know which haystack to search for this particular needle. In fact, I came away with a veritable pincushion of esoterica with which one could probe the depths of unknowing colleagues' (or Board candidates') "ignorance," if one had a taste for that sort of thing: ergophobia, toilet phobia, entophobia, acarophobia, earthworm phobia, sitophobia, genophobia, traffic phobia, college phobia, neophobia, homophobia, hysterophobia, nosophobia, aerophobia, ornithophobia, and even new-car-buying phobia! In addition to Hay's article, I uncovered articles on dysmorphophobia in many languages and in journals published in Brussels, Moscow, Warsaw, and Paris. Still, our paper could claim to be the first in American, if not in English.

Hay's paper is very fine, and we find that his discussion of dysmorphophobia is strikingly similar to ours. We concur in seeing the common underlying factor as a moderate to severe disturbance in personality and in viewing the personality of the dysmorphophobic as being typically schizoid or obsessional.

As to whether patients with frank delusions or Schneider-

ian symptoms should be classified as dysmorphophobic or some other way, an excellent term used by Riding and Munro (1) has come to my attention. They distinguish between dysmorphophobia and "monosymptomatic hypochondriacal psychoses," the latter being the psychotic equivalent of dysmorphophobia (1), and described seven patients with this syndrome who responded to pimozide.

Psychotropics and Glaucoma

SIR: Stanley W. Hyams, M.D., and Claudette Keroub, M.D., in "Glaucoma Due to Diazepam" (Clinical and Research Report, April 1977 issue), recommended use of evaluation procedures before starting systemic administration of anticholinergic drugs for patients over the age of 40. These procedures are unrealistically time-consuming, expensive, likely to be alarming to the patient, and not justified by current scientific evidence. There are certainly other possible explanations for their single case report of closed-angle glaucoma in association with diazepam, such as intrinsically increased adrenergic tone or decreased cholinergic tone. However, weaknesses in the authors' causal interpretation of the limited data are not my main concern here.

As the authors acknowledge, not a single case of glaucoma caused by diazepam has been reported previously. The benzodiazepines have few or no anticholinergic effects. The incidence of glaucoma has never been shown conclusively to be higher in groups taking psychotropic drugs than in the general population (1). The risk among the adult population of developing acute glaucoma is only 1 in 4,000, even when challenged with strong topical anticholinergics such as atropine (1). With drugs of lesser anticholinergic potency, and recognizing the much milder autonomic effects of orally administered drugs, the figure must be even lower.

A recent comprehensive review of these issues (2) included the following realistic recommendations for evaluation before the use of anticholinergic drugs in patients over the age of 40.

1. Check pupil size before and occasionally during medication to observe for dilation.
2. Check for a personal or family history of glaucoma, as well as eye examinations that included dilation.
3. Check for a history of "halos" around lights associated with eye pain.
4. If any of the above areas are suspicious, referral to an ophthalmologist for further examination is indicated.

Even if glaucoma is present, it is generally safe to proceed with psychotropic medication, provided antiglaucoma treatment is prescribed and the patient is followed by an ophthalmologist (2). Recent data also have enabled the physician to select a psychotropic drug on the basis of its relative anticholinergic activity (3). Among the tricyclics, amitriptyline has the strongest anticholinergic potency, approximately 17 times that of desipramine, which has the least anticholinergic potency. Therefore, one might choose desipramine when anticholinergic effects would be a liability.

CHARLES L. BOWDEN, M.D.
MARTIN B. GIFFEN, M.D.
San Antonio, Tex.

Drs. Hyams and Keroub Reply

SIR: We agree with Drs. Bowden and Giffen that glaucoma caused by mild anticholinergic drugs is rare and that glaucoma due to diazepam has never been reported. We emphasized this in our paper. We were also careful to point out that a causal relationship between treatment with diazepam and the development of glaucoma in our case was probable, not certain.

However, having seen the report by Friedman and Neumann (1) of two patients blinded by benzhexol, I feel that one cannot ignore the admittedly slight danger associated with these drugs.

As we and your correspondents stated, a glaucoma patient could probably continue to receive anticholinergic drugs if he was under the care of an ophthalmologist and if a simple procedure could be used to select those patients requiring special observation. The modern classification of glaucoma divides the disease into open-angle glaucoma (which is always chronic) and closed-angle glaucoma (which may be acute, subacute, or chronic). The patient we reported and those reported by Freidman and Neumann (1) had chronic closed-angle glaucoma. Bearing this classification in mind, the criteria for evaluation of patients before the use of anticholinergic drugs, which were suggested by Reid and associates and quoted by Drs. Bowden and Giffen, are not reliable. Dilation of the pupils is not a significant sign of chronic closed-angle glaucoma, except in a very advanced stage of the disease. Family history of glaucoma is more pertinent when one is dealing with open-angle glaucoma, and a history of "halos" associated with eye pain will be obtained very rarely in patients with chronic closed-angle glaucoma. Applanation tonometry, gonioscopy, and examination of the optic disc is a routine that should take less than 10 minutes. This does not seem a long time to devote to a patient who is under prolonged psychiatric care. Provocative tests are rarely necessary.

Maintenance Antipsychotic Dosage and Tardive Dyskinesia

SIR: I would like to underscore the comments made by George E. Crane, M.D., on "The Prevention of Tardive

Dyskinesia" (July 1977 issue) with a brief vignette from my clinical practice.

The patient, a 43-year-old man, had been treated with trifluoperazine, 20 mg q.h.s., for a chronic schizophrenic process. He had been on this dose for 13 years and, when I first saw him, had the most severe oral-bucco-lingual and digital dyskinesia I had encountered. His dyskinesia had been first documented only 2 years previously, but poor record keeping made it impossible to date accurately the onset of symptoms. His AIMS score in August 1975 (done as a part of an evaluation for a research project on tardive dyskinesia) was 18 out of a possible 42. Because he had been asymptomatic for over 10 years, I began to reduce his dose of medication. There was no change in his tardive dyskinesia until he had been on trifluoperazine, 10 mg q.h.s., for 3 months, when his dyskinesia rapidly improved. His AIMS score in May 1977 was reduced to 4, with only minimal oral and lingual movements.

This case shows that decreasing the maintenance antipsychotic dose may actually lead to an improvement in the symptoms of tardive dyskinesia if one waits long enough. In addition, instances of marked improvement in long-standing tardive dyskinesia raise questions about the permanence of the symptomatology. Perhaps tardive dyskinesia is always reversible, if one waits and minimizes dopamine receptor blockade for a long enough period of time.

Dr. Crane did not mention the possible role of antiparkinsonian agents in causing tardive dyskinesia. As this possibility has been suggested by Kobayashi (1), it is another reason why the physician should avoid prophylactic use and minimize the long-term use of antiparkinsonian drugs.

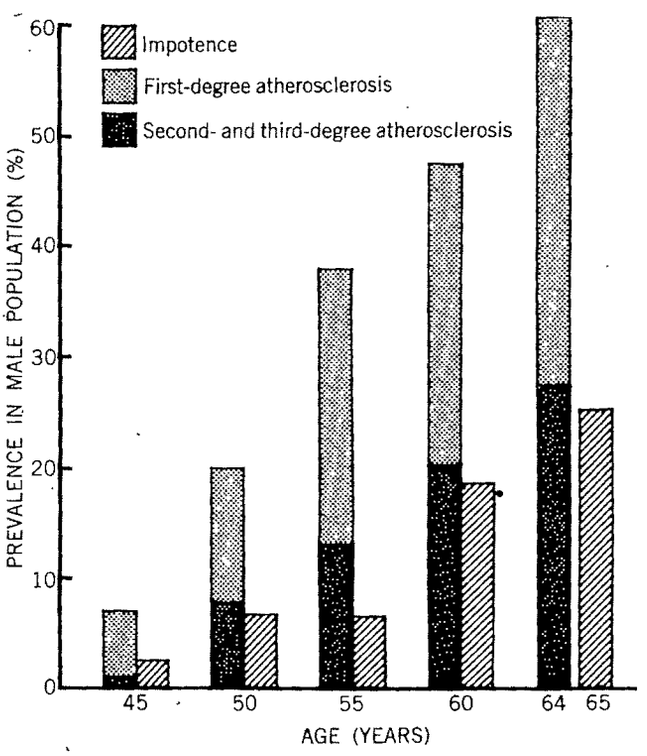
Trihexyphenidyl Abuse

SIR: "Abuse of Antiparkinsonian Drugs by Psychiatric Patients," by Katherine MacVicar, M.D. (Clinical and Research Report, July 1977 issue) reinforces observations that I made at San Quentin Prison in 1963. At that time, trihexyphenidyl (Artane) was widely enjoyed by the inmates as a drug of abuse. One man told me, "If I take five Artanes, I can see my mother. If I take 10 Artanes, I can see my girlfriend." The use of trihexyphenidyl as a psychedelic needs to be reinforced and publicized. Dr. MacVicar's paper is a valuable contribution.

THOMAS P. LOWRY, M.D.
Imola, Calif.



SIR: We read "Abuse of Antiparkinsonian Drugs by Psychiatric Patients" with much interest and would like to comment on another area of trihexyphenidyl abuse that has come to our attention. In the course of consulting at a local prison, we learned that the inmates crush the trihexyphenidyl tablets, mix the powder with tobacco, and smoke the mixture in order to obtain a high. The tablets serve as prison currency for which the inmates gamble.

We mention this form of trihexyphenidyl abuse so that clinicians who work in prisons will consider this etiological possibility when confronted with euphoria or a toxic psychosis in inmates. Clinicians should be cautious about prescribing this medication to an inmate; they should be certain that an extrapyramidal reaction is in fact present and that the inmate swallows the tablet when it is dispensed.

Correction

In the August 1977 issue, figure 1 in "Impotence Responsive to Glyceryl Trinitrate" by John W. Mudd, M.D. was incorrect. The corrected figure appears here.

BOOK REVIEWS

Modern Synopsis of Comprehensive Textbook of Psychiatry/II, *by Alfred M. Freedman, M.D., Harold I. Kaplan, M.D., and Benjamin J. Sadock, M.D. Baltimore, Md., Williams & Wilkins Co., 1976, 1,336 pp., $35.00.*

In the belief that the two volumes of the second edition of the *Comprehensive Textbook of Psychiatry* (Williams & Wilkins Co., 1975) are a bit voluminous, especially for medical students, the authors decided to condense, abbreviate, and modify its contents and publish this synopsis. The synopsis of the textbook's first edition was published in 1972; this second edition is double the size of the first, and, due to the many changes in the discipline, over 75% of the book has been rewritten. Some of the material deemed not so important for the immediate use of medical students has been eliminated, new and more cogent material has been added, and certain key material has been brought up to date. The expansion in psychiatric knowledge has been explosive, and graduate, postgraduate, and continuing education demand more attention and hold promise of even greater requirements.

Everyone is aware that there is a perplexing array of new drugs available in psychiatry. Students and practitioners must of necessity understand their properties, modes of action, and effects on the CNS. As these authors note, there is a need for the sophisticated dispensing of these agents, lest the condition they inflict be worse than the condition that called them forth. In addition to the new pharmacological agents and new advances in neurophysiology, advances in knowledge in the social sciences also clamor for attention because the environment and surroundings of the individual influence other aspects of his or her life. Along with all of this, the advances in clinical psychiatry are also noteworthy. Continuing education for all professionals is a present-day watchword as plans for national health insurance move into the foreground. More and more demands are being made on the psychiatrist as Professional Standards Review Organizations (PSROs) take form.

Thus, there is ferment in the profession as it seems slowly and painfully to wend its way back in the direction of clinical medicine, from which it evolved and by which it has been nurtured. This book takes cognizance of this fact. The authors realize that in the present state of the discipline an eclectic approach is needed; none of the components that make up the specialty can be neglected. The authors hope that this book will be "an organizing statement for the multitude of relevant variables and an initial approach to a complex model." Although its basic orientation seems to be similar to that of the first edition, the plethora of new subjects that require attention made this new book a necessity.

Random sampling of the various subjects indicates that the authors have succeeded in their efforts. There are interesting descriptions of almost everything the student requires. Not only the student but the experienced clinician will be able to refresh his or her memory of the multitude of subjects he or she is required to know. In addition, there is an excellent glossary, along with a comprehensive index. All of this goes together to make a first-class, useful synopsis of a field that is rapidly becoming more complex. One can certainly recommend this book without hesitation. It is particularly well done.

F.J.B.

My Analysis with Freud: Reminiscences, *by A. Kardiner, M.D. New York, N.Y., W.W. Norton & Co., 1977, 123 pp., $6.95.*

Dr. Kardiner's lively and frank account of his analysis with Freud in 1921 and his reflections about its effect on his life reveal intriguing aspects of the work and character of both men. Dr. Kardiner, whose early life had been traumatic and unpromising, was amazed and excited to have the opportunity to be analyzed by Freud. He expected to be awed by the great man but was pleasantly surprised by Freud's friendliness, modesty, and humor and by his willingness, on occasion, to talk about himself and his colleagues. Kardiner has never understood why Freud discussed personal matters with him; he learned from Freud's other analysands that this was not Freud's practice.

The humility and critical self-appraisal that Freud conveyed to Kardiner contrasted with Freud's expectation of loyalty and with the authority he assumed for the growth and development of psychoanalysis. Freud controlled the economic fate and professional status of analysts. Although Kardiner has enormous admiration for Freud's genius, he thinks it unfortunate that he had so much power because it led to rivalry and infighting among Freud's followers. In spite of their competitiveness, however, they worked together diligently and learned from each other; Dr. Kardiner states that he feels privileged to have learned from them. He describes with enthusiasm his participation in the activities of the Vienna Psychoanalytic Society. While he was in Vienna, the first series of didactic courses ever offered by a psychoanalytic group was organized.

Dr. Kardiner is grateful for the salubrious effect on his personal and professional life of his contacts with Freud the man, the therapist, the investigator, and the teacher. Freud's insights and understanding helped Kardiner to overcome his fears and inhibitions and to become more confident and assertive. Thus, his personal life was enriched and he was more free to pursue his career as an analyst.

Kardiner believes that Freud's momentous contributions to psychoanalysis can be divided into two categories: the delineation of intrapsychic processes and the emphasis on the importance of the environment in human development. It is likely that Dr. Kardiner's appreciation of the effect on his life of early trauma and his capacity to adapt to it accounts in part for his interest in the role of culture in human development. His outstanding contributions in this field are well known.

Dr. Kardiner ends his book with a plea for more field investigations of a variety of cultures. He believes that from such studies we will be able to develop directives for child

rearing and identify successful patterns of adaptation; he feels that this information will help us cope with the ills of our times. Although I agree with Dr. Kardiner that such studies should be encouraged, I am not as optimistic as he about what we can expect from them. In his enthusiasm for field studies, he recommends that we stop studying people on the couch. I disagree with this recommendation and wonder how Dr. Kardiner reconciles it with his own valuable experience on the couch.

REBECCA Z. SOLOMON, M.D.
Hartford, Conn.

Chemotherapy in Psychiatry, *by Ross J. Baldessarini, M.D. Cambridge, Mass., Harvard University Press, 1977, 196 pp., $9.95.*

This is a very well organized, extremely readable book that is a must for every psychiatric resident and for the practicing psychiatrist. It will also be an extremely useful addition to the reference library of the internist and the family practitioner. Dr. Baldessarini has organized the information in this volume by drug types, starting with the antipsychotic agents and continuing through the lithium salts, antidepressant agents, and antianxiety drugs. In the concluding chapter he comments briefly on a series of special issues, such as geriatric and pediatric psychopharmacology.

The information provided is given in adequate detail and in a sufficiently condensed form that it is accessible and useful for rapid review in a given clinical situation. Each chapter starts with a description of the various chemicals in each class of therapeutic agents, including their chemical structure, followed by a discussion of their pharmacological activity. The author provides detailed directions for clinical use of these drugs, including a careful discussion of toxicity and side effects, an assessment of the relative dosage strengths, and the efficacy of currently available psychoactive compounds.

I believe that most skilled psychopharmacologists will agree with the various recommendations made in this volume regarding the use of the different chemical agents. Dr. Baldessarini draws a fine line between an adequately conservative approach toward the use of these compounds and the necessary emphasis on their significance in the management of serious psychotic and neurotic illnesses. If there is a fault to be found with the volume it is that, although the bibliography is nicely organized by topics, it is not referenced to specific statements in the body of the text. However, the bibliography is comprehensive and will provide the serious student of psychopharmacology with an excellent set of references for detailed information on the subjects covered in the book.

BERNARD C. GLUECK, M.D.
Hartford, Conn.

The Annual of Psychoanalysis, Vol. IV, *edited by the Chicago Institute for Psychoanalysis. New York, N.Y., International Universities Press, 1976, 500 pp., $17.50.*

Like the three volumes preceding it, this book covers a wide range of topics in psychoanalysis. Some aspects are covered more completely than others; child analysis, for example, is given relatively little attention. Although most of the articles are from the Chicago Psychoanalytic Institute, some individual chapters are written by other distinguished authors.

This book holds the reader's interest in each chapter, regardless of the area dealt with. Most of the chapters contain good historical background, complementing the first section, Psychoanalytic History. Part two, Clinical Theory, deals with the narcissistic disorders as differentiated from oedipal fixations. In various subsections the authors discuss in some detail the beginnings of Freud's work and compare conditions in Freud's era and now. The chapter by Benedek is particularly intriguing: she discusses not only women analysts but also some of the latest thinking about feminine and masculine psychology. This is interesting reading in the light of various liberation movements.

Section three, Developmental Psychology, presents a fascinating exchange of ideas between Freud and Piaget. The book on the whole is not totally Freudian; it deals with other areas in which psychoanalysis could be or has been involved. The section titled Clinical Psychoanalysis devotes itself primarily to the postencephalitic syndrome, about which we know very little but to which psychoanalysis can contribute a good deal. There is a pertinent section titled Psychoanalytic Education, which is concerned mainly with the selection of analytic candidates. This is an issue about which there is still disagreement; the discussion of the usefulness of single and group interviews presented here indicates that both seem to be of value.

The section on Interdisciplinary Research includes two chapters, one on psychoanalysis and communication science and the other on aspects of the dynamics of prejudice. The final section has two chapters that would be of great interest to the scholar, "The Theme of Incest in the Myth of Osiris" and "The Suicide of Richard Corey," an in-depth analysis of a poem.

I feel that this volume would be an excellent addition to one's library. Some of the reading is a bit tedious in parts, but it is nevertheless an enticing book and well worth reading.

STUART M. FINCH, M.D.
Tucson, Ariz.

The Unconscious God: Psychotherapy and Theology, *by Viktor E. Frankl. New York, N.Y., Simon & Schuster, 1975, 159 pp., $6.95.*

Although the most recent of Dr. Frankl's books to be published in the English language, *The Unconscious God* is actually one of the first books by the renowned Austrian existential psychiatrist and founder of logotherapy. First published as *Der Unbewisste Gott* in 1947, the present edition contains both an English version of the original work (essentially unchanged except for minor alterations) and an extensive postscript in which the author discusses the development and maturation in his thinking over the intervening decades. The two sections of the book serve to complement each other; they are followed by an extensive updated bibliography.

The first section of the book, the English version of the original German edition, consists of several chapters. Here the author develops his thesis that a religious sense is rooted in the unconscious depths of every man and that only by awareness of this dimension can man be fully understood in terms of his uniqueness, his capacities, and his response to

life and a meaning beyond himself. The chapter titled "The Spiritual Unconscious" is especially pertinent; it contains a concise and helpful discussion of the concept of dimensional ontology that is invaluable in unifying any multidimensional approach. Other chapters are devoted to the essence of existential analysis, existential analysis of conscience and dreams, the transcendent quality of conscience, unconscious religiousness, and psychotherapy and theology.

The second part of the book contains Dr. Frankl's reflections on the tenets proposed in the first section in the light of his present thinking. He also presents supportive evidence gained by studies assessing the value of logotherapy as a treatment modality. This becomes rather tedious at times because many studies are cited that arrive at what appear to be gross generalizations in support of logotherapy. This is not to question the value or efficacy of logotherapy but, rather, to alert the reader to be discerning of the more substantial evidence in support of this treatment approach.

This is not an easy book to read, and the problem seems to derive as much from aspects of the author's presentation as from the complexity of the subject matter. Although this edition is written in English, much of the author's thinking remains in German, often creating a sense of unfamiliarity until one becomes aware of the style and makes the necessary adjustments. Of more concern, however, are aspects of the author's reference to other treatment modalities, particularly psychoanalysis. His statements in this regard seem overgeneralized, challenging, and, at times, provocative. As a result the author tends to detract from his own thesis and runs the risk of alienating readers who would otherwise be quite open to serious consideration of the many profound ideas in this book.

HALLIE E. MOORE, M.D.
Hartford, Conn.

Psychotherapy Versus Behavior Therapy, *by R. Bruce Sloane, Fred R. Staples, Allan H. Cristol, Neil J. Yorkston, and Katherine Whipple. Cambridge, Mass., Commonwealth Fund in cooperation with Harvard University Press, 1975, 259 pp., $10.50.*

As the variety of therapeutic interventions available to psychiatrists continues to increase, it is essential that criteria be developed for fitting the proper treatment to the proper patient. Ultimately, these criteria will come out of research. Until the last two decades, research in psychiatry provided little practical guidance for the clinician. Anecdotal studies in which various practitioners described the impact of a particular intervention on a particular group of patients provided general guides to treatment but proved nothing. Later studies using control groups and documenting the effectiveness of particular interventions as compared with no intervention were much more useful. However, these still did not provide the clinician with guidance as to the best treatment for the individual patient. Recently, behavioral scientists have begun to study the relative effectiveness of different interventions on people with similar disorders. These studies will ultimately contribute to the development of effective and rational psychiatric interventions.

In *Psychotherapy Versus Behavior Therapy*, Sloane and associates concisely but thoroughly describe their efforts to discover the effectiveness of two modes of intervention with neurotic patients. They approach their task with considerable sophistication. In the first chapter, "How Psychotherapy Has Been Studied," they review the methodological problems involved in psychiatric research. Their description of the task of defining a patient population, a treatment modality, and outcome variables is excellent. This chapter alone should definitely be read by the psychiatrist.

Fully aware of the pitfalls of psychiatric research, the authors devised an elaborate project in which they compared patients receiving classical psychoanalytically oriented individual psychotherapy with patients receiving behavior therapy and with a control group of patients who were waiting to be placed in therapy. The 11 major features that the authors consider to be distinctive to their study were designed to avoid the pitfalls characteristic of so much psychiatric research. In this study the authors were careful, patient, and exhaustive. They were scrupulously fair in not structuring the study so that the results would favor one intervention. The methodologies used to define the patient population, treatment modality, and outcome criteria are carefully described, as are methods for using independent assessors and test modalities.

The results of the study are interesting and may even be surprising to some, but they do not come close to resolving the question of what is the best way to treat neurotic patients. Psychotherapy and behavior therapy turned out to be more or less equally effective in treating the research population, and both modalities were more effective than no treatment. However, the value of this book does not lie in its presentation of results. *Psychotherapy Versus Behavior Therapy* is an important contribution to psychiatry because it beautifully demonstrates how interventions in psychiatry can be studied if researchers are dedicated enough and patient enough to commit themselves to thorough follow-up research. It is the best available brief guide to dealing with methodological problems in research in psychiatry and should serve as an inspiration to those willing to commit themselves to the difficult but absolutely essential task of studying which interventions work best with which patients.

SEYMOUR L. HALLECK, M.D.
Chapel Hill, N.C.

Current Psychiatric Therapies, Vol. 16—1976, *edited by Jules H. Masserman, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1976, 334 pp., $28.50.*

This 16th volume of what has deservedly come to be an essential part of any psychiatric library is introduced by Judd Marmor with a chapter on "The Psychotherapeutic Process." The rest of the book covers a broad range of subjects and treatment modalities with an almost cookbook practicality. Dr. Marmor demonstrates his own eclecticism when he lists the common denominators of psychotherapy as a good patient-therapist relationship, release of tension, cognitive learning, operant reconditioning, suggestion and persuasion, identification with the therapist, reality testing, and emotional support.

The remainder of the book is divided into sections labeled Childhood and Adolescence; Adult Psychotherapies; Drug, Hormonal and Somatic Therapies; Addictions; Family, Group and Institutional Therapies; and Psychiatric Vectors in Population Control. Some pathologies appear in more than one section; the mentally retarded and their treatment possibilities are discussed in part one and again in part two. It is heartening to note that George Tarjan's insistence that this neglected group of patients has potentials that can be

developed seems to have been adopted. Menolascino and Simmons and Tymchuk are anything but pessimistic in their contributions about the possibilities of dealing therapeutically with these people. Similarly, Cancro's chapter, "Comprehensive Therapy of the Schizophrenic Syndrome," and Ban's "Pharmacotherapy of Schizophrenia," offer succinct and practical therapeutic suggestions for the management of the most prevalent of the psychiatric illnesses.

In the second section there is a series of brief discussions of various types of adult psychotherapies, including television therapy, primal therapy, and existential therapy; there is even a short chapter on humor in psychotherapy. There are good clinical illustrations for many of the points the authors make.

The section on drug, hormonal, and somatic therapies is especially to the point; the two chapters on the indications for lithium therapy, its use, its management, and methods of preventing untoward side effects should be required reading now that more and more conditions are being treated with this chemical. Equally useful are the chapters on haloperidol and injectable fluphenazines.

The sections on addictions and on psychiatric vectors in population control round out the broad coverage provided in this volume, but an especially interesting series of chapters appears in the section on family, group, and institutional therapies. Dr. Masserman gets this section off to a good start by a chapter that includes a case report of a sophisticated female patient whose endless dynamic ramblings were helpfully interrupted when he insisted on treating a puncture wound of her foot with tetanus antitoxin before he would let her proceed. Some of the succeeding chapters recognize the changing loci of appropriate treatment by discussing psychotherapy in the home, hotel therapy, and the use of folk healers as associate therapists. The chapter on correctional psychiatry understandably is directed more at stating the problems than at offering solutions, but an unusual aspect of the discussion by Dy and Herzberg is their emphasis on the importance of the psychiatrist's understanding the problems of the guards and the institution as well as those of the inmates.

The editor and the authors are to be commended for this extremely useful series.

C.H. HARDIN BRANCH, M.D.
Santa Barbara, Calif.

Foundations of Biochemical Psychiatry, *edited by David S. Segal, Ph.D., Joel Yager, M.D., and John L. Sullivan, M.D. Boston, Mass., Butterworths, 1976, 337 pp., $19.95.*

This volume adds further support to the biochemical basis of psychiatric illness. The book consists of seven major sections and is multiauthored. It is a compilation of a series of very important and classic review articles dealing with various aspects of biological psychiatry. Most of the material has been previously published; the virtue of this volume is that it makes the articles available in a handy form. Clearly the editors have made a contribution by bringing these papers together. It is a good introduction to the biochemical foundations of the discipline for residents in psychiatry.

The book begins with an introduction to fundamental concepts: abnormal behavior, biochemical considerations, and research strategies. The second section begins with a clinical description of schizophrenia. L.L. Heston reviews the genetics of schizophrenic and schizoid disease, and R.J. Wyatt, B.A. Termini, and J.M. Davis review the literature from 1960 to 1970 on biochemical and sleep studies in schizophrenia. A review by E.H. Ellinwood, Jr., on amphetamine psychosis as a multidimensional process appears next, followed by S.H. Snyder, S.P. Banerjee, H.I. Yamamura, and D. Greenberg on the effects of drugs, neurotransmitters, and schizophrenia. In addition, L. Stein and C.D. Wise review their data on the possible etiology of schizophrenia in relationship to the noradrenergic reward system by 6-hydroxydopamine.

The third major section of the book deals with the affective disorders. E.S. Gershon, D.L. Dunner, and F.K. Goodwin review the genetic contributions of affective disorders; J.J. Schildkraut reviews the catecholamine hypothesis of affective disorders; and F.K. Goodwin, D.L. Murphy, H.K.H. Brodie, and W.E. Bunney, Jr., review the relationship of L-dopa, catecholamines, and behavior of depressed patients. B. Shopsin, S. Wilk, G. Sathananthan, S. Gershon, and K. Davis critically review the catecholamine hypothesis, and A. Coppen then reviews the role of indoleamines in affective disorder. A review by D.S. Janowsky, M.K. El-Yousef, J.M. Davis, and H.J Sekerke relating a cholinergic-adrenergic hypothesis of mania and depression follows.

Section four deals with the neuroses and their classification, including G.D. Miner's review of the evidence for genetic components in neuroses and D.M. Warburton's discussion of modern biochemical concepts of anxiety. Section five reviews briefly the hyperactive child syndrome. S.H. Snyder and J.L. Meyerhoff suggest how amphetamine acts in minimal brain dysfunction, and L.E. Arnold, P.H. Wender, K. McCloskey, and S.H. Snyder compare the comparative efficacy of levo- and dextro-amphetamine in the hyperkinetic syndrome.

Section six deals with the subject of alcoholism. A review by D.W. Goodwin, F. Schulsinger, L. Hermansen, S.B. Guze, and G. Winokur on alcohol problems in adoptees raised apart from alcoholic biological parents highlights this section. Section seven deals with the subject of psychoendocrinology, including E.J. Sachar's discussion of hormonal changes in stress and mental illness. In addition, references and a glossary are provided.

In summary, this convenient volume contains a large selection of important reviews published in various journals. Although it contains little that is new, the book serves a useful purpose. It is recommended for those with a special interest in biological psychiatry and for psychiatric hospitals and medical libraries.

E.F. DOMINO, M.D.
Ann Arbor, Mich.

Drug Interactions: Clinical Significance of Drug-Drug Interactions and Drug Effects on Clinical Laboratory Results, 3rd ed., *by Philip D. Hansten, Pharm.D. Philadelphia, Pa., Lea & Febiger, 1975, 378 pp., $11.50 (paper).*

This book delivers more than the title promises; in addition to drug interactions, which are covered in the first half of the volume, drug effects in clinical laboratory tests are described in part two, which is somewhat shorter than part one. Coming at a time of increasing consciousness of the importance of drug interactions, increasing use of potent pharmaceuticals, and increasing reliance on laboratory tests, this work fills an obvious need. Even on cursory review one can understand why it has had three editions since 1971 and has already been translated into Japanese and German.

This is a reference book based on the use of the index; the author states in the first paragraph that one must use the index. Following the instructions one finds the book logical in arrangement and easy to use because the print is clear and the paper of good quality. Part one consists of sections 10–20 lines long covering drug interactions. Each section contains a few lines on the mechanism of interaction, a statement on clinical significance, and a statement on management; if no special management is required this is stated. Virtually every assertion is documented with one or more references; the total bibliography is extensive.

To become acquainted with the volume the reader might turn to a familiar drug group, such as the phenothiazines, in the index. There he or she will find that some 23 drugs interact with this group and that the phenothiazines have an effect on 16 tests of blood and urine. Because bold type is reserved to identify well-documented interactions of major significance, it is important that none of the names of the interacting drugs is printed in bold type. Six of the interacting drugs are listed in italic type, which means that they produce interactions of moderate significance; the names of the rest of the drugs in this list are printed in ordinary type because they are considered of minor significance.

On the other hand, the list of interactions found under tricyclic antidepressants shows bold type for interactions with bethanidine, epinephrine, guanethidine, and levarterenol, and the monoamine oxidase inhibitors as a group have seven drugs in bold type in their listing. Similarly, we see at a glance that disulfiram requires special attention when given with diphenylhydantoin or oral anticoagulants.

There is much more of similar interest in this book, but one must remember that it is not a general text on adverse reactions and that the descriptions are limited to interactions among drugs, even when one might expect some comment, e.g., concerning the three-way interaction that occurs when a person taking diphenylhydantoin to control epilepsy is given phenothiazines. Only the interaction between the two drugs is mentioned, so the clinician will have to keep in mind the more significant reaction between the convulsive tendency of the patient and the phenothiazines. Similarly, the description of the interaction between ethyl alcohol and diphenylhydantoin ends with the comment that "epileptics receiving diphenylhydantoin (DPH) who drink heavily should be watched more closely for decreased anticonvulsant effect." This relates only to the interaction between the two drugs; it does not extend to the very serious interaction between epilepsy and alcohol because epileptic patients who drink heavily represent a special problem.

The psychiatrist who reads carefully might raise such questions as why chocolate and banana are listed in the index but processed cheese is not (at least I did not find it), but these are minor details. The language of the text is such that it more than compensates for any quibbles that might be raised; it is clear and explicit without any hint of package-insertese (to coin a term), and it alerts the clinician but still leaves a healthy degree of flexibility for exercise of judgment. Keeping these and other current matters in mind one can give thanks as he or she wanders through the pages of this book that "this adverse potential [for drug interaction] is realized in a relatively small proportion of cases receiving the interacting combinations." However, one cannot forget that the lists of interactions for many drugs are long and that many of the names are printed in bold or italic type. In the nature of such things these lists can only grow longer and more demanding of attention as time goes on.

As documentation grows it will be less and less possible to attribute adverse effects to simple drug idiosyncrasy or underlying disease. We have learned in the past few years that we must ask every new patient what drugs he or she has been taking. This promises to become an ongoing question in the context of treatment. For dealing with this source of growing complexity in medicine there will be an increasing need for the type of reference provided by *Drug Interactions*.

HENRY BRILL, M.D.
Islip, N.Y.

Pharmacology: Drugs Affecting Behavior, *by Conan Kornetsky. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1976, 258 pp., $18.95.*

Knowledge about the effect of drugs on behavior is burgeoning at such a rapid rate that writing about it immediately introduces problems of focus and organization. Dr. Kornetsky is not deterred by these two challenges. He states at the outset that he is aiming his remarks at a nonmedical audience. However, he feels, correctly, that many physicians and some psychiatrists could also benefit from this overview of psychopharmacology. He first sets out to devise a primer of the principles of general pharmacology; this is a model of clarity and succinctness. He describes such fundamentals as absorption, distribution, receptor sites, dose-effect curves, and the impact of tolerance, hypersensitivity, idiosyncratic reactions, allergic responses, and genetics.

Following the exposition of these general pharmacological principles, which apply to any drug, the author goes on to put in proper perspective the role of placebo and nonspecific factors in determining drug response. Because most of the drugs used in the treatment of mental illness have actions involving the autonomic nervous system, Dr. Kornetsky devotes an entire chapter to reviewing this system and the pharmacology of the drugs that act primarily on it. A brief and somewhat spotty chapter on the neurophysiology and biochemistry of the CNS completes this concise primer of fundamentals, which the reader needs in order maximally to understand the remainder of the volume.

Dr. Kornetsky chooses to categorize psychotropic drugs as antipsychotic, antidepressant, and antianxiety medications, narcotic analgesics, hypnotics, and sedatives, with an additional section on the amphetamines. This choice differs little from the choice of most other investigators and teachers writing about psychotropic agents. In addition, however, he provides chapters on alcohol, anti-epileptic medications, and drugs for the treatment of minimal brain dysfunction (the hyperkinetic syndrome) as well as an extensive chapter on the nonmedical use of drugs. These are welcome supplements and serve to make this a truly well-rounded volume about drugs that affect behavior. An additional attractive aspect of the volume is the glossary of street terms. Such colorful terms as "cartwheels" for amphetamine tablets scored crossways, "double trouble" for Tuinal (a barbiturate capsule containing both secobarbital and amobarbital), "TNT" for heroin, and "Acapulco gold" for high-grade marijuana are only a few of the very descriptive and authentic terms used to describe various forms of drugs.

It might be argued that Dr. Kornetsky could have focused in greater depth on some of the areas he writes about rather then attempting to touch so many bases. Actually, the broad panorama covered by the author is one of the book's strengths. Although many students and investigators who

are interested in antipsychotic and antidepressant agents might not be particularly interested in anti-epileptic drugs or minimal brain dysfunction, the material is here for them if they need it. On the other hand, if the reader does not want to review so many disparate fields, he or she can learn a great deal without reading all 13 chapters because most of the chapters stand alone.

This monograph is not for the seasoned expert or experienced researcher. However, it is certainly an invaluable addition for medical students, psychologists, nurses, social workers, and enlightened laypeople who want to obtain a broad overview of the most current knowledge about drugs and behavior.

SIDNEY MALITZ, M.D.
New York, N.Y.

Current Developments in Psychopharmacology, Vol. 2, *edited by Walter B. Essman and L. Valzelli. New York, N.Y., Spectrum Publications (Halsted Press, John Wiley & Sons, distributor), 1976, 248 pp., $20.00.*

This volume is one of a series of annual publications consisting of invited contributions from distinguished scientists and clinicians actively working in different areas of psychopharmacology. Volume 2 has seven chapters, some of which are better and/or more interesting than others. One of the most informative and timely chapters is that of Kuhar, Simon, and Rommelspacher on the location, function, and pharmacology of central cholinergic neurons. This chapter is followed by two considerably less timely papers on the pharmacology and clinical use of flurothyl. Although the use of flurothyl in the treatment of psychiatric disorders as an alternative to ECT has been virtually abandoned by now, Adler states that flurothyl is still a useful investigative tool in the evaluation of compounds with potential anti-petit-mal efficacy, in studying the various processes involved in learning and memory, in quantitating cerebral excitability, and in exploring the biochemical and neurophysiological mechanisms underlying the seizure process.

A new general theory suggesting that amphetamine increases the repetition rate of all motor activities with the ultimate result of increasing response rates within a decreasing number of categories is put forward by Lyon and Robbins. If the new theory is correct, complex behavioral chains or behaviors requiring longer pauses, such as sleep, feeding, and certain types of social behavior, will be eliminated first under the influence of amphetamine; behaviors capable of repetition without long pauses will dominate for a transient period. Whether this new theory of amphetamine action offers any advantages over the existing ones remains to be seen.

There is a short and concise chapter on the relationship between the animal pharmacological profile and clinical effects of neuroleptic drugs. On the basis of a careful analysis of experimental data on 81 neuroleptic drugs, Janssen and Van Beuer suggest a relationship between the ED_{50} on the apomorphine antagonism test in dogs and the potency and/or duration of action of neuroleptic drugs. Similarly, the ratio of palpebral ptosis to catalepsy may serve as a useful index of relative sedative versus neurological effects, the ratio of norepinephrine antagonism to amphetamine antagonism as an index for relative adrenolytic activity versus antipsychotic activity, and the ratio of the jumping box test to the apomorphine antagonism test as an index for relative neurological versus antipsychotic activity. It would be of great practical significance if these observations could be supported by further evidence.

This volume also contains a long-overdue review of sensory psychopharmacology by Robinson and Sabat. The literature they review covers a period extending from 1958 to 1973, with an emphasis on major psychophysical findings and results of evoked response studies. The final chapter reviews some evidence indicating a relation of brain dopamine with depression and mania.

This is obviously not a book for the student but for the teacher, not for the practicing psychiatrist but for the research worker.

THOMAS A. BAN, M.D.
Nashville, Tenn.

The Effect of the Man-Made Environment on Health and Behavior, *edited by Lawrence E. Hinkle, Jr., M.D., and William C. Loring, Ph.D. Atlanta, Ga., U.S. DHEW Center for Disease Control, 1977, 315 pp., $3.25 (paper).*

Physicians have long maintained an interest in understanding environmental factors that affect health and disease. This book explores what is known about factors in the residential environment that might offer opportunities to reduce risk or promote health. It considers housing from the standpoints of physical design and social patterns.

The authors review a range of data and models and attempt to use Leighton's concept of community disintegration to understand the social distress of some large public housing projects. Kasl's chapter summarizes some of what is known about crowding, noise, size of domestic unit, division of residential space, control of residential space, proximity to a range of services, mass relocations, and demographic match between individuals and the local social context.

Much of this work is in such an early state that it provides only a suggestive basis for public policy decisions. The authors adduce evidence showing that a territory which functions as a neighborhood, with social attachments and organizations, yields an environment with a lower risk of accidents, violence, and disease than does the socially undefined space around some large housing projects. They suggest that certain factors of spatial arrangement can promote the development of affiliations and neighborhoods, but the situation is far from clear. Administrative actions that promote simultaneous mass migrations, or "relocations," appear to impede neighborhood development and can yield significant risks.

Cassel's review of the data concerning the risks of a range of physical diseases in various residential environments suggests a model involving individual affiliations, status hierarchies, degree of population adaptation to a particular context, and range of group support systems.

Hinkle's chapter suggests that some residential environments are able to shorten life, sicken it, damage babies, and interfere with the bonding process but that our knowledge is not sufficient to define environments that would reliably reduce such risks. Apparently a residential environment should be warm, commodious, quiet, private, peopled with kith and kin, and serviced with a range of amenities and assistances to daily activities. It should also be free of lead paint and accident hazards.

Damon's chapter tries to determine some limits. How noisy can the environment be before a hazard exists? How crowded can rooms be before damage is regular? It is not

clear whether true thresholds exist or whether the hazards act in a summative or interactive manner.

In *The Effect of the Man-Made Environment on Health and Behavior* Hinkle and Loring provide a helpful overview of an area of knowledge just barely opened. The tabulated data and exploratory models should be of interest to physicians and to those concerned with public housing policy.

NORRIS HANSELL, M.D.
Champaign, Ill.

Support Systems and Mutual Help: Multidisciplinary Explorations, *edited by Gerald Caplan and Marie Killilea. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1976, 315 pp., $19.50.*

This book, which consists of 13 chapters by 11 different authors, brings together ideas, research findings, and practice principles that relate to support systems and mutual help groups. As a whole, it serves as a reminder that competence and mental well-being can be increased by understanding and making use of the wide variety of helping systems that are in existence but are usually not included in program planning; in fact, their techniques are often ignored or spurned by professionals.

In the first chapter, titled "The Family As Support System," Gerald Caplan reminds us that the extended family is not so dead as we supposed, that the majority of older people either live with or very close to one of their children, and that more than 75% of people over 65 feel themselves to be in good health and can play an active role in public and private affairs. He goes on to give a clear and concise listing of the ways in which the family can help in the growth and development of its members. In the final section of his chapter Caplan pleads for suitable housing so that members of extended families can live close to each other; he also decries the underutilization of retired people.

The next several chapters could be titled collectively, "Everything You Always Wanted To Know About Mutual Help Organizations But Were Afraid To Ask." The second chapter is a review of the literature and cites 220 references. After a rather confusing beginning, it outlines the characteristics of mutual help groups, suggesting that the typologies range from the analytic on one end of the scale to the repressive-inspirational on the other. Another way of organizing the groups places those which provide crisis help in one category and those which aid the permanently stigmatized in another. A third group would be those which aid people trapped in some form of self-destructive behavior. This very comprehensive chapter reminds us that social movements attempt to bind people together and provide meaning to life as well as support. There is also a useful comparison between orthodox psychotherapy and self-help group therapy.

The next chapter, "Religious Aspects of Support Systems," suffers the usual fate of the conference report that is not very well edited: because the reader was not at the conference there are vital gaps that are not bridged by the written word. However, the chapter is interesting, with discussions ranging from the dependent immersion that takes place in Pentecostal groups to the religious ritual of the Academy Awards.

In "Self Help Treatment Programs," Dumont reminds mental health professionals that "unless we can accommodate to and find some common ground with this [self-help] movement, we will become increasingly cloistered, self-serving and irrelevant." In "Going Public and Self Help," Spiegel clearly articulates the dilemma of the stigmatized patient who alternates between being a victim and denying his or her handicap. The addition of the role of teacher for others with a similar handicap helps the individual come out with the message, "I am this, but I am more." This applies to gay people, paraplegics, and a host of other silent and stigmatized minorities.

Deathbed scenes through the ages are the subject of a well-written chapter by Ruth Caplan, followed by two chapters describing self-help organizations for middle-class people. Parents Without Partners provides support for many single parents, and Recovery, Inc., binds together, encourages, and inspires former mental patients. The description of this semireligious group is particularly interesting.

In his chapter, "Transition States," Weiss gives details of his Seminars for the Separated, which sound very useful. Chapters 11 and 12 discuss various aspects of a program for widows, including a valuable analysis of various styles of helping. The chapter by Richards on "Peer Consultation Among Clergy" reminds us of the marked stress felt by the modern-day clergy, who find themselves with few unique skills, waning status, and an occupational identity crisis. It describes the supportive interaction possible between dyads of bishops in the Episcopal Church and suggests that this model could be effectively reproduced between clergy at all levels.

The last chapter, largely derived from Caplan's experiences in Israel during the Yom Kippur War, discusses the organization of civilians in time of war or disaster. It is worth reading as soon as one overcomes the temptation to dismiss the content as irrelevant because "It couldn't happen here."

Overall, this is a worthwhile book for psychobiosocial caregivers who are secure enough to admit and embrace the power of the people as an effective force to improve community mental health.

N. MICHAEL MURPHY, M.D.
Albany, N.Y.

Psychopharmacology in the Practice of Medicine, *edited by Murray E. Jarvik, M.D., Ph.D. New York, N.Y., Appleton-Century-Crofts, 1977, 516 pp., $20.50.*

Some books are known in the trade as "how-to" books. This one should properly be considered a "what's-it" book. Unlike most multi-authored books on psychopharmacology, which abound these days, this one has been well planned as an appreciation of psychopharmacology. It provides a broad view of what psychopharmacology is concerned with, what some of its experimental techniques are, and what impact psychopharmacological knowledge has made on clinical problems—not a small ambition but one that has been realized in a most satisfactory way.

Thirty-five "minireview" chapters are grouped into four major sections. The initial section of 3 chapters is introductory; the second considers the experimental use of these drugs in 12 chapters; the third has 13 chapters devoted to various uses of psychotherapeutic drugs; and the fourth section consists of 7 chapters describing social drugs. Each section and each chapter is introduced by brief editorial comment pointing out the salient points to be covered and setting the context. A very short section of concluding editorial remarks completes the book. Each chapter reads very

well and hews to the main theme, no doubt reflecting excellent editing. Although the list of contributors includes many of the most accomplished researchers in the field, each has submerged his or her special interests to the cause of reviewing the entire field; the book is not a collection of individual papers. References are limited in number but provide an adequate base for expanded reading on any given subject.

This format serves admirably for examining the many aspects of the field. The price is that what is gained in breadth is lost in depth. This deficiency is most evident in the sections on clinical applications of psychotherapeutic drugs: some areas are covered far too sketchily. When a number of chapters are grouped together to cover a single topic, such as the 5 chapters concerned with affective disorders or the 2 concerned with opiate abuse, these subjects are given reasonably full treatment.

The most obvious use for this book is to form a basis for a course on psychopharmacology suitable for students or psychiatric residents. Each chapter could provide the advance reading for a more detailed discussion in lectures. The book could also well be read by those working in the field, simply to expand their appreciation of its diversity. Reading it fills one with a sense of awe for what has been learned during the past two or three decades as well as a sense of humility about what still needs to be known.

LEO E. HOLLISTER, M.D.
Palo Alto, Calif.

Computed Brain and Orbital Tomography: Technique and Interpretation, *by Carlos F. Gonzalez, M.D., Charles B. Grossman, M.D., and Enrique Palacios, M.D. New York, N.Y., John Wiley & Sons, 1976, 270 pp., $29.00.*

Computerized axial tomography has been hailed as the greatest advance in radiology since Roentgen's discovery of X rays. The technique uses an extremely small beam of X rays and replaces film with radiation detectors that measure the attenuated intensity of the beam as it passes through the skull and brain. The beam is moved to and fro as well as being rotated. A computer solves a large series of simultaneous equations to create a density value for each point in a two-dimensional matrix with anywhere from 160 to 320 points per side. When this is displayed on a cathode-ray oscilloscope, the picture is that of a horizontal section of the brain showing the ventricles, the sulci, and other anatomical structures. Pathological processes appear as areas of increased or decreased density. The use of intravenous contrast media will "enhance" certain lesions, increasing their apparent density. The process of scanning is carried out in several sections usually separated by 13 mm, thus allowing visualization of the brain from the posterior fossa to the vertex. The process has the advantage of low dosage of radiation and of being a noninvasive, completely safe procedure.

This new radiological procedure has progressed in its application so rapidly that it is difficult to keep up with its progress. A new journal has recently been organized dealing solely with this technology. This book is one of several that have appeared recently. It opens with a relatively brief section on basic physical principles, followed by a section on correlative anatomy and computerized transaxial (CT) scanning. The remainder of the volume is dedicated to changes in specific diseases, e.g., tumors, vascular disease, and trauma.

In the short time of its existence, CT technology has revolutionized approaches to neuroradiological diagnosis. Although it does not eliminate angiography or pneumoencephalopathy, it has greatly reduced the requirement for these procedures, both of which carry a measurable risk. It has also made it possible to literally look into the head without risk and to yield information not obtainable by any other radiological method.

This volume is well printed and contains a wealth of illustrations covering most of the common and some of the uncommon neurological disorders. Because of the rapid progress in this field, it may very well be outmoded in a short time, but for the moment it is an adequate statement of present capability.

DAVID D. DALY, M.D., PH.D.
Dallas, Tex.

The Right to Treatment for Mental Patients, *edited by Stuart Golann and William J. Fremouw. New York, N.Y., Irvington Publishers (Halsted Press, John Wiley & Sons, distributor), 1976, 239 pp., $16.95.*

In recent years the mental health establishment has witnessed an increasing intrusion on the part of insurance carriers, government agencies, and judicial actions. These intrusions have ostensibly been justified on the basis of upgrading and improving mental health care. Although the actions have generally been well meaning, they have often created additional problems and fallen far short of their original goals.

One of the recent controversies that has drawn attention is the right to treatment issue for involuntary patients. This issue was first clearly enunciated in the *Wyatt v. Stickney* decision (1–3) and later expanded in *Donaldson v. O'Connor* (4, 5). It is in this context that the Amherst Conference on Right to Treatment was convened; this book is the result of that conference.

The contributors to the book represent a variety of disciplines including psychology, psychiatry, sociology, and the law, indicating the far-reaching aspects of this legal question. The papers themselves deal with the historical, legal, social, and political perspectives and their impact on mental health delivery systems.

Of particular interest is a chapter by Stickney, the Commissioner of Mental Health of Alabama and defendant in *Wyatt v. Stickney*. He presents an enlightening view of the case itself and highlights the struggle of political and legal forces, with the mental health system a victim in the middle. This theme is expanded in Mechanic's essay, in which he notes the conflict between ideology and pragmatism in the situation. Although the courts might mandate changes, the funding might not be forthcoming; legislators might see a more economical way of dealing with fiscal dilemmas by abolishing state institutions and not providing aftercare arrangements. Mechanic's conclusion is that litigation has only short-range benefits, but social change is more valuable in the long run. Halpern raises a further issue of interest, namely, the care of the mentally retarded, who are often voluntary patients and are in need of basic rehabilitation services.

Overall, the reader comes away from this book with a greater understanding of the issues but probably with more questions than answers. One additional feature of the book is the inclusion of court decision source material on the significant cases for reference. This book informs well without being overwhelming regarding a topic of increasing importance.

Origins of Concepts in Human Behavior: Social and Cultural Factors, *by Mark D. Altschule. Washington, D.C., Hemisphere Publishing Corp. (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1977, 200 pp., no price listed.*

This collection of essays on the most diverse of subjects is drawn together by the interest and sensibility of Professor Altschule. The papers are glittering nuggets gleaned from his reading in the history of medicine over some 20 years. His aim in this collection is to illustrate the ineluctable interplay between medical ideas and *Zeitgeist*. Here, in "The Pneuma Concept of the Soul," he traces the peregrination of the idea of soul=breath through most of the major cultural systems of the world. Another variation of this theme, that of ethnicity and mental disease, is explored in the case of "George Cheyne and His English Malady." Derived largely from his own experience, Cheyne's description of hypochondriacal depression fell on receptive ears in 1733, crystallizing some sentiments about Englishmen general to the time (i.e., that they were self-destructive, moody, and predisposed to insanity). Altschule shows how these notions persisted well into the nineteenth century despite the lack of evidence and the irritation expressed by some English medical writers.

In "Huron Ideas About the Unconscious Mind" and "The Early History of Psychiatric Treatment," Altschule delights in the demonstration of J. L. Borges' thesis, namely, that all great ideas (e.g., Freud's dream theory) create their own precursors. Here are the titles of some other chapters to give a further idea of Altschule's range: "Acupuncture in the Western World Up to a Century Ago," "The Singular Case of James Tilly Matthews, A Clear Paranoid (Whose 19th-Century Mechanical Delusions Are Those of a Newton Gone Mad!)," "Acedia—Its Evolution from Deadly Sin to Psychiatric Syndrome."

Altschule's style is scholarly but not pedantic. There are moments when he is more bookish than literary, but these are few and far between. Furthermore, Altschule possesses a sharp wit that he unlimbers on occasion. I think this volume will be of interest to those who pursue the history of ideas or who seek to broaden their perspective on current clinical phenomena. I wish this book into the hands of those who usually do not read "that sort of thing." Not only is it useful reading, it is enjoyable as well.

JOHN R. NEILL, M.D.

Dialogues for Therapists: Dynamics of Learning and Supervision, *by Margaret J. Rioch, Winifred R. Coulter, and David M. Weinberger. San Francisco, Calif., Jossey-Bass, 1976, 233 pp., $12.95.*

Margaret Rioch is a distinguished psychologist well known for her pioneering work in the field of group relations. A practicing psychotherapist, she has drawn from personal knowledge of such teachers as Harry Stack Sullivan, Frieda Fromm-Reichmann, Edith Weigert, Martin Buber, and Zen Buddhist scholars Daisetz T. Suzuki and Hubert Benoit. As leader of a seminar for beginning psychotherapists, she has achieved a creative union between her expertise in psychotherapy and her knowledge of group theory. She and her colleagues Winifred Coulter and David Weinberger have compiled this book detailing the most meaningful elements of a series of her seminars, including comments on the ongoing process between Dr. Rioch and her students as the seminars developed. The result is a valuable addition to our knowledge of psychotherapy and how it might be taught.

The book is organized into dialogues between instructor and students centering on critical elements in the therapeutic process as exemplified in case presentations. Subjects such as initial contracts, transference and countertransference, therapeutic strategies, and termination are discussed. This familiar material is refreshed by Dr. Rioch's unbiased approach—she seems as comfortable in behavioral theory as in analytic—and by her steady insistence that the underlying feelings and process between both participants in the therapy relationship must be examined. These dialogues go beyond the therapist's feelings in his or her relationship with the patient to include the group process generated within the seminar.

Rioch's point is that "in order to be 'fully present,' to use Martin Buber's term, it is necessary to clear away the fears and preoccupations, the blind spots and the prejudices, with which beginning therapists, as well as more experienced ones, are heavily burdened. . . . We have to wipe the mirror clean before we can see what is reflected." She believes that the seminar's process, including the students' relationship with her, will inevitably mirror the difficulties and successes of the therapeutic work under discussion. What is especially unique here is that because of the dialogue form we can actually see the process through which the students learn to work with the complex interrelationship between their therapeutic work and the group supervision, between their patients' feelings and attitudes toward them and their own feelings and attitudes toward their seminar colleagues and Dr. Rioch. The art of a skilled and experienced teacher is palpable as each episode unfolds. Her methods are gentle yet incisive, a model for clinical supervisors in any setting.

Dialogues for Therapists is an excellent volume for beginning therapists; many of the cases represent classic difficulties in the therapeutic encounter. Additionally, teachers of psychotherapists may want to try Dr. Rioch's group model in their own supervisory work. Those who already are involved in group supervision will benefit from seeing how an expert in group process can use this knowledge to enhance the learning opportunities in a seminar setting. Of particular note are two remarkably frank evaluative chapters, one on supervision failures and the other on the "antitherapeutic" aspects of the seminar itself. Both of these demonstrate how competition, jealousies, and anger can be magnified by the group context and how unspoken negative fantasies about the instructor can limit creativity and support "no-risk" learning. As one student commented when the seminar members were briefly contemplating how much they were influenced and inhibited by Dr. Rioch's presence, "The real problem is not how nice it would be *without* her, but how to live *with* her. And not only with her, with all the other authorities, too."

Perhaps the most valuable aspect of the book for me was

the opportunity it afforded to learn more about what this very wise woman understands to be the essential elements in the therapeutic process. The book is full of statements that go beyond her immediate task in the seminar yet provide its best teaching. For example, in the course of talking about specific goals of therapy she says, "In the back of my head, I keep the idea that if he [the patient] gets over the few hurdles in the interpersonal world, he may go on to something much better, namely, a lack of concern for himself altogether." The experienced therapist may find himself or herself scanning the more elementary and task-oriented parts of this book for more of these gems. This is at once the strength and weakness of this fine volume.

ARTHUR D. COLMAN, M.D.
Sausalito, Calif.

Alcoholism Problems in Women and Children, *edited by Milton Greenblatt, M.D., and Marc A. Schuckit, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1976, 274 pp., $19.50.*

This book is another excellent choice in the series of Seminars in Psychiatry. The book is divided into two sections, the first dealing with alcoholism in women and the second with adolescent drinking problems.

Beginning with a general overview of alcoholism in women, the chapters in the first section explore in detail the problems, theories, and treatment of alcoholic women. In contrast to the traditional view that many alcoholic people drink to gratify passive-oral dependency needs, Wilsnack presents her theory that conflicts and tensions related to sex roles contribute to drinking problems among women today. Whereas some men drink to satisfy their need for power, some women drink to increase feelings of traditional femininity or womanliness.

Beckman presents an excellent description of the social and psychological aspects of alcoholism and the influence of the spouse and mother on the alcoholic picture, providing negative evidence on the old concept of the "alcoholic personality." The authors of the following two chapters discuss theories concerning the biological aspects of alcoholism as they pertain to women. A few studies point to the stress of the menstrual cycle as a possible precipitating factor for alcoholism in certain women. On the basis of studies indicating changes in alcohol metabolism associated with different phases of the menstrual cycle, the authors hypothesize a relationship between alcohol and depression via changes in MAO levels during the menstrual cycle. The first part of the book ends with a short presentation on lesbianism and alcoholism and a discussion of treatment programs for alcoholic women.

The second part of the book starts with a general review of the extent of drinking problems among adolescents. The authors explore the social, interpersonal, and psychological factors involved in teenage drinking. They make the observation that if an individual is ever going to drink, he or she will likely begin to do so before graduation from high school. They also observe that girls in the 15–18-year-old group are changing in terms of the number who drink, type of beverage consumed, frequency of drinking, and drinking to intoxication. In fact, the female adolescent now surpasses her male counterpart on some variables.

A chapter dealing with parental influences on the drinking patterns of their children presents a model assuming a multilevel process of parent effects, including socioeconomic, sociocultural, family interaction, and the individual parent's behavior. This is followed by a short review by Winokur of several recent genetic studies providing evidence for a genetic causative factor in alcoholism and no evidence to indicate that rearing is important.

The last chapter is perhaps the most interesting. It discusses fully the fetal alcohol syndrome and the seriousness of alcoholism in pregnancy. Several studies and observations made during the past several years provide strong evidence that a congenital syndrome of abnormalities can result from heavy alcohol intake by pregnant women. The syndrome may include the following: short birth length and low birth weight, continuing failure to thrive, craniofacial abnormalities, joint and limb anomalies, cardiac defects, mental deficiency, and delayed motor development. The author emphasizes that because of these characteristic facets, diagnosis is relatively easy but very important because it clarifies etiology and provides the opportunity for recommending against subsequent pregnancies for alcoholic women who continue to drink heavily.

In general this is an excellent review of recent and important contributions in the field of alcoholism. It should be read by those who work in the field.

Farmington, Conn.

Developmental Disabilities: Psychologic and Social Implications, *edited by Daniel Bergsma, M.D., and Ann E. Pulver, M.H.S. New York, N.Y., Alan R. Liss, 1976, 188 pp., $18.00.*

This book presents the proceedings of a conference of the National Foundation-March of Dimes sponsored by the Johns Hopkins Medical Institutions in Baltimore, Md., March 1–2, 1976. The 16 papers are organized into four sections: Medical Aspects, Pre-Adult Disability, Individual and Family Needs, and Societal Reaction. The papers are generally of high quality, timely, and well written. However, the authors have some difficulty in properly classifying the papers into the organizational framework, and there is some redundancy.

The overall theme of the conference was the significance of social factors in the understanding of developmental disability and in planning for service delivery. This is perhaps best expressed by Leon Eisenberg, who draws the distinction between illness and disease, i.e., between organic pathology and the reaction of the patient and society to the patient's illness.

Individual papers include an epidemiological study in British Columbia by James R. Miller; a review of the literature dealing with the reactions of the nondisabled toward those who are by Stephen A. Richardson; a review of the British literature dealing with the reactions of parents to the handicapped child by Sheila Hewett; a survey of physical, intellectual, psychological, and social problems in the United Kingdom by Elizabeth M. Anderson; personal experience with the problems of adolescence in the physically disabled by Thomas E. Strax; the roles of the family and health professionals in the decision-making process by Raymond S. Duff; an analysis of the obstacles to effective supporting psychological services by Albert J. Solnit; a review of health care received by children with developmental disorders and their families by Ivan B. Pless; a history of the medical treat-

ment of the orthopedically handicapped by Saul Benson; an attack on current practices of testing and education by Edmund W. Gordon; alternative forms of health care by Robert Morris; the issues in three lawsuits dealing with the rights of the handicapped by Kathleen G. Ursin; the use and misuse of scientific knowledge in shaping public policy by Elizabeth M. Boggs; recommendations for architectural redesign of environments by Sandra C. Howell; recommendations for public education by Lowell S. Levin; and a discussion of the value of epidemiological studies in designing and evaluating health services for the handicapped by Leon Eisenberg.

This volume will be most valuable to the general physician and health care program administrator. It stresses the importance of social factors and personal relationships with handicapped clients in evaluating and treating the full ravages of their disability. However, the book is long on broad ethical, moral, and theoretical issues and short on immediate, concrete program recommendations for the social engineering required to deal with problems of the handicapped.

GERALD R. CLARK, M.D.
Elwyn, Pa.

A Primer on Chemical Dependency: A Clinical Guide to Alcohol and Drug Problems, *by Joseph Westermeyer, M.D., M.A., M.P.H., Ph.D. Baltimore, Md., Williams & Wilkins Co., 1976, 225 pp., $11.95 (paper).*

In his introduction Westermeyer informs us that this book is intended for "the medical or surgical practitioner, whether generalist or specialist . . . [as well as] your spouse, parent, child, or friend, . . . dependent patients and their families, . . . other workers in the health field—nurses, psychologists, medical social workers, . . . [students in these fields, and] law enforcement officials, clergy, counselors, or sociologists." All things to all men? Hardly. Unfortunately, this attempt weakens several potentially useful books. Focus of both subject matter and audience is lacking; the result is simplification, at times to the point of distortion.

What is striking to me is that hidden within the text is the basis of an excellent simple introduction to the problems of alcoholism. On the basis of an examination of the references, I believe this was the author's original intention. For example, of the 19 references in the chapter titled "Chemical Dependency Syndrome," only two deal with drugs other than alcohol. Similar if less extreme ratios are seen in the references for other chapters. In addition, the author seems most sure when discussing alcohol. He scants the complex pharmacological-personality-social relationships of other drugs and the issue of use as distinct from abuse. An attempt at a unified theory of drug abuse, subsumed under the rubric "chemical dependency," is premature, particularly if it is offered in an introductory text.

WILLIAM A. FROSCH, M.D.
New York, N.Y.

Alcoholism and the Brain, *by A.E. Bennett, M.D. New York, N.Y., Stratton Intercontinental Medical Book Corp., 1977, 86 pp., $9.75.*

The author of this book is the respected director of the neuropsychiatric foundation that bears his name; he has enjoyed a long career in neurology and psychiatry. This slender volume is directed mainly toward physicians with the expressed hope of increasing their understanding of the impact of heavy chronic doses of alcohol on the brain and to balance what the author feels is an overemphasis on psychological and social circumstances in the field of alcoholism.

Part of the book reviews many of the ancient statements made by psychiatrists and researchers. Many authors in the field of alcoholism (myself included) feel compelled to engage in this ritual. Since the same names and statements pop up again and again, we should question whether those of us who write about this subject do not ourselves suffer from repetitive compulsivity that is often a part of the problem in alcoholism.

Dr. Bennett's main thesis is that it is impossible to treat alcoholic people successfully unless one first treats their physical addiction by medical means. He allows that once this is accomplished, psychological and social therapies are appropriate. This book is thus an accumulation of old material that describes in detail the acute and chronic effects of alcohol on the brain. I designate the material as old because those of us who have followed Dr. Bennett's career recognize that he does not include the more recent studies on the effects of alcohol on the brain. Although this book's appeal is to a limited audience, many of us need to be reminded that along with its psychological and social ramifications, alcohol abuse definitely affects the brain and the nervous system.

MORRIS E. CHAFETZ, M.D.
Washington, D.C.

Theories of Group Processes, *edited by Cary L. Cooper. New York, N.Y., John Wiley & Sons, 1976, 272 pp., $9.95 (paper).*

This book is an academic study of T groups. It focuses on these groups in community organizations and business but does not say much about group psychotherapy. There are 10 chapters and 14 authors, and the goals and quality of the articles are inconsistent. The extensive bibliography after each chapter will acquaint the psychiatrist with some of the extensive literature by nonpsychiatrists.

This book is a must for the serious group therapy researcher and for serious students of group therapy. The practitioner and casual student of group therapy will find a few interesting and helpful ideas; they will find the book is worth a quick reading.

Dual Problem: marked agitation with depression

...a common problem in psychiatric practice.

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please see last page of this advertisement.

Dual-action TRIAVIL

containing perphenazine and amitriptyline HCl

Marked agitation accompanying depression is a common problem in psychiatric practice, a problem often requiring dual-action therapy to effectively cope with both components of the disorder. TRIAVIL 4-25 helps treat both. A formulation particularly suited to psychiatric practice when higher doses are required, TRIAVIL 4-25 affords the psychiatrist the opportunity to treat marked agitation—each tablet containing 4 mg of the tranquilizer, perphenazine—while helping to relieve the coexisting depression with 25 mg of the tricyclic antidepressant, amitriptyline HCl.

helps treat both the marked agitation and the depression

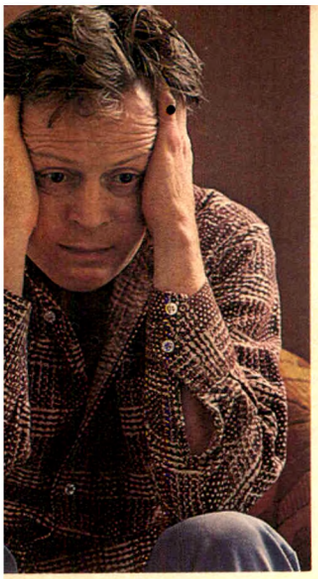
An antidepressant alone may be adequate when ıe accompanying anxiety is mild, but dual-action 'RIAVIL should prove more appropriate when ıe anxiety or agitation (accompanying depression) moderate or severe.

The four formulations of TRIAVIL permit the sychiatrist to treat a relatively broad spectrum f depressed patients who manifest symptoms ınging from moderate anxiety to severe agitation, nd allow for individualized dosage adjustment.

he advantages of dual-action 'RIAVIL in psychiatric practice.

/ith TRIAVIL, as anxiety or agitation with depres- ɔn is relieved, the patient may become more ccessible and cooperative. Many symptoms such as ısomnia, fatigue, anorexia, and functional G.I. com- laints are frequently alleviated; symptomatic relief ıay enable the patient to function more effectively in is daily activities, and the psychotherapeutic process self may be aided.

TRIAVIL simplifies therapy; encourages compliance.



A single tablet encourages patients to take medication properly and reduces the risk of dosage confusion and error. Cost of therapy to the patient is usually less than when the components are prescribed individually. To date, clinical evaluations of TRIAVIL have revealed no undesirable reactions peculiar to the combination.

Treatment with TRIAVIL– a balanced view.

TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. It is not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please see following page.

for moderate to severe anxiety or agitation and depression

DUAL-ACTION Triavil®

containing perphenazine and amitriptyline HC

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinso have been reported and can usually be controlled by the concomitant effective antiparkinsonian drugs and/or by reduction in dosage, but times persist after discontinuation of the phenothiazine.

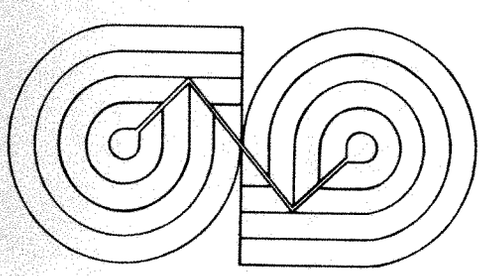
Tardive dyskinesia may appear in some patients on long-term thera may occur after drug therapy with phenothiazines and related agen been discontinued. The risk appears to be greater in elderly patients or dose therapy, especially females. Symptoms are persistent and in patients appear to be irreversible. The syndrome is characterized by mical involuntary movements of the tongue, face, mouth, or jaw. In tary movements of the extremities sometimes occur. There is no k treatment for tardive dyskinesia; antiparkinsonism agents usually do n viate the symptoms. It is advised that all antipsychotic agents be disc ued if the above symptoms appear. If treatment is reinstituted, or dos the particular drug increased, or another drug substituted, the syndrom be masked. Fine vermicular movements of the tongue may be an earl of the syndrome. The full-blown syndrome may not develop if medica stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, ery urticaria, eczema, up to exfoliative dermatitis); other allergic rea (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reac peripheral edema; reversed epinephrine effect; hyperglycemia; end disturbances (lactation, galactorrhea, gynecomastia, disturbances o strual cycle); altered cerebrospinal fluid proteins; paradoxical excit hypertension, hypotension, tachycardia, and ECG abnormalities (qui like effect); reactivation of psychotic processes; catatonic-like states nomic reactions, such as dry mouth or salivation, headache, an nausea, vomiting, constipation, obstipation, urinary frequency or tinence, blurred vision, nasal congestion, and a change in pulse rate; adverse reactions reported with various phenothiazine compounds, b with perphenazine, include grand mal convulsions, cerebral edema phagia, pigmentary retinopathy, photophobia, skin pigmentation, and of ejaculation.

The phenothiazine compounds have produced blood dyscrasias topenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosi lia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur afte term administration of some phenothiazines. Although it has not reported in patients receiving TRIAVIL, the possibility that it might should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia also been reported.



Amitriptyline: Note: Listing includes a few reactions not reported f drug, but which have occurred with other pharmacologically similar tri antidepressant drugs and must be considered when amitriptyline is ad tered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpi myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neu cular:* Confusional states; disturbed concentration; disorientation; delu hallucinations; excitement; anxiety; restlessness; insomnia; nightm numbness, tingling, and paresthesias of the extremities; peripheral pathy; incoordination; ataxia; tremors; seizures; alteration in EEG pa extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH diuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred disturbance of accommodation; increased intraocular pressure; constip paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic* rash; urticaria; photosensitization; edema of face and tongue. *Hemat* Bone marrow depression including agranulocytosis; leukopenia; eos lia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastr tress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; p swelling; black tongue. Rarely hepatitis (including altered liver functi jaundice). *Endocrine:* Testicular swelling and gynecomastia in the breast enlargement and galactorrhea in the female; increased or dec libido; elevated or lowered blood sugar levels. *Other:* Dizziness, wea fatigue; headache; weight gain or loss; increased perspiration; u frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* cessation after prolonged administration may produce nausea, headach malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an over should be admitted to a hospital as soon as possible. Treatment is s matic and supportive. However, the intravenous administration of 1- of physostigmine salicylate is reported to reverse the symptoms of tr antidepressant poisoning. Because physostigmine is rapidly metaboliz dosage of physostigmine should be repeated as required particularly threatening signs such as arrhythmias, convulsions, and deep coma re persist after the initial dosage of physostigmine. On this basis, in overdosage with perphenazine-amitriptyline combinations, sympt treatment of central anticholinergic effects with physostigmine sal should be considered.

J 6TR06 R3 (DC6613212)

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

Phillip H.* was an engineer with a problem... but now he's solving problems for industry

Patient name	Phillip H.*	**Sex:** Male	**Age:** 29
Marital status S. (M.) W. D.		**Occupation:**	Mechanical engineer

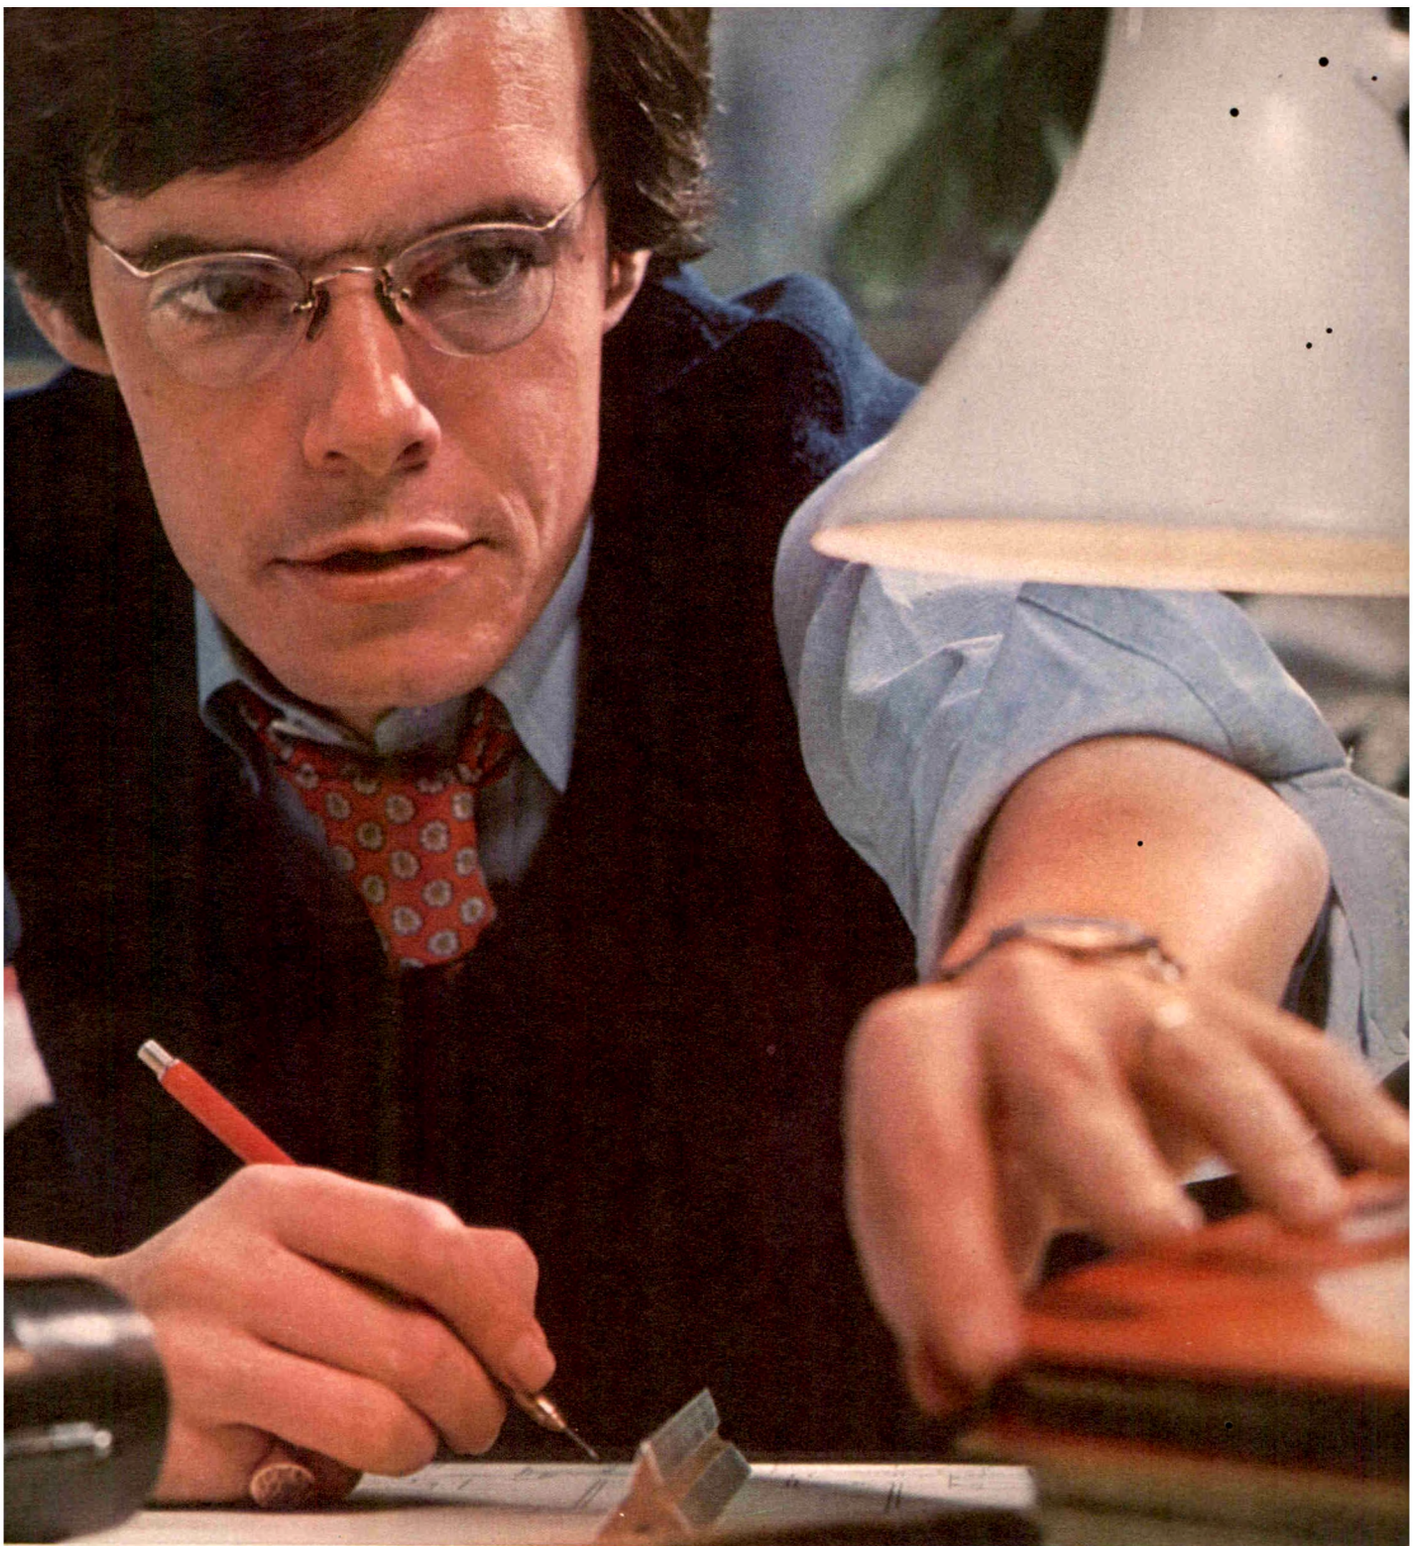
History: Studious, bright, only son; much older sister. Father an invalid; mother, a successful business woman. A "loner" with multiple psychosomatic illnesses, he started dating late and married first girl friend, several years older

Onset of illness: Upset at wife's pregnancy, expressed strong guilt feelings after her miscarriage; said people accused him of "murder." Unable to eat or sleep properly, felt he was "losing his mind." Unable to work, obtained leave of absence and was referred to psychiatrist

Diagnosis: Acute schizophrenia

Treatment: LOXITANE® Loxapine Succinate 25 mg b.i.d. increased to 50 mg t.i.d. over 2 weeks. Supportive psychotherapy three times a week

Therapeutic course: First week, eating and sleeping better. Guilt feelings expressed le often. Mild akathisia responded to appropriate antiparkinson medication



Second week, communicating better. Feared that "fatherhood w develop into rivalry," feared loss of wife's love

Third week, no delusions or hallucinations, relating better, bu to only one person at a time

Affect still blunted at one month, otherwise asymptomatic. LOXITANE decreased to 50 mg b.i.d.; antiparkinson medicati continued

Follow-up: 10 weeks; at work for one week, seems to be adjusting well. A parkinson medication discontinued; psychotherapy weekly LOXITANE 25 mg t.i.d.

*Not an actual patient. The collection of clinical d upon which this simulation is built illustrates the action of LOXITANE® Loxapine Su as reported in clinical studies.

He's adjusting well in his job, and with psychotherapy and medication, he also can be helped to feel more secure, less threatened in his relationships with others.

Loxitane®

Lederle

For the symptoms that interrupt careers

See LOXITANE prescribing information on following page for indications, warnings and precautions and for more detailed information concerning side effects.

Loxitane®
LOXAPINE SUCCINATE
Lederle

For the symptoms that interrupt careers

Recommended Daily Dosage

Initial Dosage	MILD 10 mg b.i.d.	MODERATE 10 mg t.i.d. or q.i.d.	SEVERE 25 mg b.i.d.
First 7 to 10 Days	Increase dosage until psychotic symptoms are controlled Dosage should not exceed 250 mg/day Usual dosage during titration: 50 to 150 mg/day		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day. Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Brief Summary

LOXITANE® Loxapine Succinate Capsules
OR
LOXITANE® C Loxapine Hydrochloride Oral Concentrate

Description: A dibenzoxazepine compound, representing a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines.

Indications: For the manifestations of schizophrenia. Loxapine has not been evaluated for the management of behavioral complications in mental retardation, and therefore cannot be recommended.

Contraindications: In comatose or severe, drug-induced depressed states (alcohol, barbiturates, narcotics, etc.); and in individuals with known hypersensitivity to the drug.

Warnings: In Pregnancy: Safe use during pregnancy or lactation has not been established; in pregnancy, nursing mothers, or women of child-bearing potential, weigh potential benefits against possible hazards to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg./kg., doses which approximate the usual human dose but which are considerably below the maximum recommended human dose. **In Children:** Studies have not been performed in children; therefore this drug is not for use below the age of 16.

May impair mental and/or physical abilities, especially during the first few days of therapy; warn ambulatory patients about activities requiring alertness (*e.g.*, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

Precautions: Use with extreme caution in patients with history of convulsive disorders; seizures have been reported in epileptics receiving this drug at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy. Has an antiemetic effect in animals; this effect in man may mask signs of overdosage of toxic drugs and obscure conditions such as intestinal obstruction and brain tumor. Use with caution in patients with cardiovascular disease. Increased pulse rates in the majority of patients receiving antipsychotic doses and transient hypotension have been reported. In hypotension requiring vasopressor therapy, preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine. Possibility of ocular toxicity from loxapine cannot be excluded at this time, therefore observe carefully for pigmentary retinopathy and lenticular pigmentation (observed in some patients receiving certain other antipsychotic drugs for prolonged periods). Because of possible anticholinergic action, use with caution in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

Adverse Reactions: CNS: Adverse effects other than extrapyramidal, infrequent. Drowsiness, usually mild, may occur at beginning of therapy or when dosage is increased, usually subsiding with continued therapy. Incidence of sedation is less than that of certain aliphatic phenothiazines and slightly more than piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported. Extrapyramidal reactions during use of this drug have been reported frequently, often during the first few days of treatment. In most patients, these involve Parkinson-like symptoms such as tremor, rigidity, excessive salivation, masked facies, akathisia, usually not severe and controlled by dosage reduction or use of antiparkinson drugs in usual dosage. *Less frequent, but more severe:* Dystonias, including spasms of muscles of neck and face, tongue protrusion, oculogyric movement; dyskinesia in the form of choreo-athetoid movements. These sometimes require reduction or temporary withdrawal of drug dosage in addition to appropriate counteractive drugs. *Persistent Tardive Dyskinesia:* May appear in some patients on long-term therapy, or after therapy has been discontinued; the risk greater in the elderly, especially females, on high dosage. These symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of tongue, face, mouth or jaw (*e.g.*, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements, sometimes accompanied by involuntary movements of extremities). No known effective treatment; discontinue all antipsychotic agents if these symptoms appear. The necessity to reinstitute treatment or increase dosage, or switch to a different antipsychotic agent, may mask syndrome. If medication is stopped when fine vermicular movements of the tongue occur, the syndrome may not develop. *Cardiovascular:* Tachycardia, hypotension, hypertension, lightheadedness, syncope. A few cases of EKG changes similar to those seen with phenothiazines have been reported, not known to be related to loxapine use. *Skin:* Dermatitis, edema (puffiness of face), pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of uncertain etiology seen in a few patients during hot summer months. *Anticholinergic:* Dry mouth, nasal congestion, constipation, blurred vision—more likely to occur with concomitant use of antiparkinson agents. *Other:* Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of uncertain etiology.

Dosage and Administration: Administered orally, usually in 2 to 4 divided doses a day. Adjust dosage to patient's need relative to severity of symptoms and history of response to antipsychotic drugs. Recommended initial dosage is 10 mg. b.i.d.; in severely disturbed patients up to 50 mg. daily. Increase dosage during first 7 to 10 days until psychotic symptoms are controlled. Usual therapeutic and maintenance range is 60 mg.-100 mg. daily. More than 250 mg. daily is not recommended. Maintenance dosage should be at lowest level to control symptoms; many patients have been maintained on 20 mg. to 60 mg. daily.

LOXITANE C Oral Concentrate should be mixed with orange and grapefruit juice shortly before administration. Use only enclosed calibrated dropper.

The Rape Victim

by Elaine Hilberman, M.D.

Mythologies about rape are legion. However, in recent years behavioral scientists have accumulated a body of information about rape and about an unfolding series of reactions experienced by the victim after rape. The aim of this concise, tightly reasoned book is to summarize what is now known about the needs and experiences of the victim and her family, and to provide a framework in which the clinician can more knowledgeably supply assistance and support. This document, published by the American Psychiatric Association, is the result of a project of the Association's Committee on Women.

Pointing out that the profound impact of rape stress is best understood in the context of rape as "a crime against the person and not the hymen," Dr. Hilberman sees rape as the ultimate violation of the self short of homicide, as an act of violence and humiliation in which not only is the victim's very existence threatened, and her inner and most private space invaded, but her autonomy and control are totally demolished. Dr. Hilberman shows that if and when the victim reports the crime, she is confronted with a complex series of yet additional stresses growing out of her contact with the hospital, police, courts, media and community opinion. Additionally, her crisis differs from other crises in that her usual social support system is likely to be disrupted. Her immediate needs are for empathy and safety, and a sense of control over what is happening in her dealings with the several agencies. Dr. Hilberman shows that in the absence of sensitivity to these needs, the experience of reporting becomes another assault.

This book presents a professional, sobering, and balanced picture of the problems of the rape victim and details what the clinician must know—about local hospital policy, criminal justice procedure, rape statutes, and community attitudes and services—in order to be able to treat victims with an understanding of the larger context in which rape occurs.

ELAINE HILBERMAN, M.D., *is in the Department of Psychiatry at the University of North Carolina School of Medicine.*

Haldol®
(haloperidol)
tablets/concentrate/injection

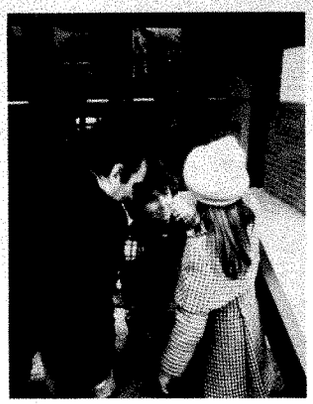
For prompt control with minimal risk of adverse reactions

Highly effective in a wide range of psychotic symptoms,[1-10]
such as hallucinations, delusions, suspiciousness, hostility, mania, psychomotor agitation, etc., in both acute and chronic disorders.

Usually leaves patients more responsive to rehabilitation...[1,2]
better able to care for themselves and take part in therapy sessions.

Helps avoid long-term hospitalization.[1,3-5]
It is often possible to release the patient for treatment as an outpatient after a short confinement. HALDOL haloperidol controls his psychotic symptoms, usually leaving him sufficiently alert to carry on normal functions.

Permits aggressive titration to effective dosage levels,[3,6]
up to 100 mg/day orally, to achieve optimal response when patient is inadequately controlled at lower dosage...to help you promptly control and stabilize new patients.



Common side effects easily controlled.[1,3,6-8]
Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

*Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Reduces risk of several treatment problems.[1,2,6,7,9]
Transient hypotension occurs rarely and severe orthostatic hypotension has not been reported. Marked sedation is rare, although some instances of drowsiness have been reported. In addition, with chronic use, it is unlikely to cause hepatic damage, serious hematologic reactions, photosensitivity reactions and skin rashes...and has minimal effect on renal function.

Please turn page for information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions.

Important: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

Haldol®
(haloperidol)
tablets/concentrate/injection

For prompt control of psychotic symptoms with minimal risk of adverse reactions

A Dosage Form for Every Need:

5 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg., 5 mg. and 10 mg.

A tasteless, odorless, colorless liquid concentrate for better patient acceptability: 2 mg. per ml.

A rapid-acting injection for psychiatric emergencies: 5 mg. per ml., with 1.8 mg. methylparaben and 0.2 mg. propylparaben per ml., and lactic acid for pH adjustment to 3.4±0.2.

Contraindications: Severe depression, coma, CNS depression due to centrally-acting depressants, Parkinson's disease, hypersensitivity to the drug.

Warnings: ***Usage in Pregnancy:*** Safe use in pregnancy or in women likely to become pregnant has not been established; use only if benefit clearly justifies potential hazards. Infants should not be nursed during drug treatment.

Usage in Children: Safety and effectiveness not established; not recommended in pediatric age group.

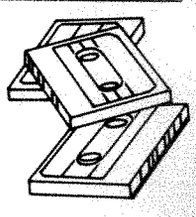
Combined Use with Lithium: Patients receiving lithium plus haloperidol should be monitored closely for early evidence of neurological toxicity.

General: Bronchopneumonia, sometimes fatal, has followed use of major tranquilizers, including haloperidol. Prompt remedial therapy should be instituted if dehydration, hemoconcentration or reduced pulmonary ventilation occurs, especially in the elderly. Decreased serum cholesterol and/or cutaneous and ocular changes have been reported with chemically-related drugs, although not with haloperidol. Mental and/or physical abilities required for hazardous tasks or driving may be impaired. Alcohol should be avoided due to possible additive effects and hypotension.

Precautions: Administer cautiously to patients: (1) with severe cardiovascular disorders, due to the possibility of transient hypotension and/or precipitation of anginal pain (if a vasopressor is required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur); (2) receiving anticonvulsant medication since HALDOL haloperidol may lower the convulsive threshold; (3) with known allergies or a history of allergic reactions to drugs; (4) receiving anticoagulants. Concomitant antiparkinson medication, if required, may have to be continued after HALDOL haloperidol is discontinued because of different excretion rates; if both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson drugs, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used for mania in cyclic disorders, there may be a rapid mood swing to depression. Severe neurotoxicity may occur in patients with thyrotoxicosis receiving antipsychotic medication, including HALDOL haloperidol.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions:* Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which were usually mild to moderately severe and usually reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally, extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Antiparkinson drugs may be required. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Withdrawal Emergent Neurological Signs:* Abrupt discontinuation of short-term antipsychotic therapy is generally uneventful. However, some patients on maintenance treatment experience transient dyskinetic signs after abrupt withdrawal. In certain cases these are indistinguishable from "Persistent Tardive Dyskinesia" except for duration. It is unknown whether gradual withdrawal will reduce the occurrence of these signs, but until further evidence is available haloperidol should be gradually withdrawn. *Persistent Tardive Dyskinesia:* Although rarely reported with HALDOL haloperidol, tardive dyskinesia may appear during or after long-term therapy. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and sometimes appear irreversible; there is no known effective treatment and all antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent. *Other CNS Effects:* Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports of mild, usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis; agranulocytosis rarely reported and only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice reported. ***Dermatologic Reactions:*** Maculopapular and acneiform reactions, isolated cases of photosensitivity, loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

The injectable form is intended only for acutely agitated psychotic patients with moderately severe to very severe symptoms.



IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed. HALDOL tablets are manufactured by McNeil Laboratories Co., Dorado, Puerto Rico 00646. 5/77

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

A CONSISTENT PATTERN OF PATIENT RESPONSE

Because psychotherapy holds so many variables, predictability of patient response to adjunctively administered medications is a much-sought objective. The consistency of patient response to Librium® (chlordiazepoxide HCl) therefore makes it a good choice when clinically significant anxiety interferes with therapy.

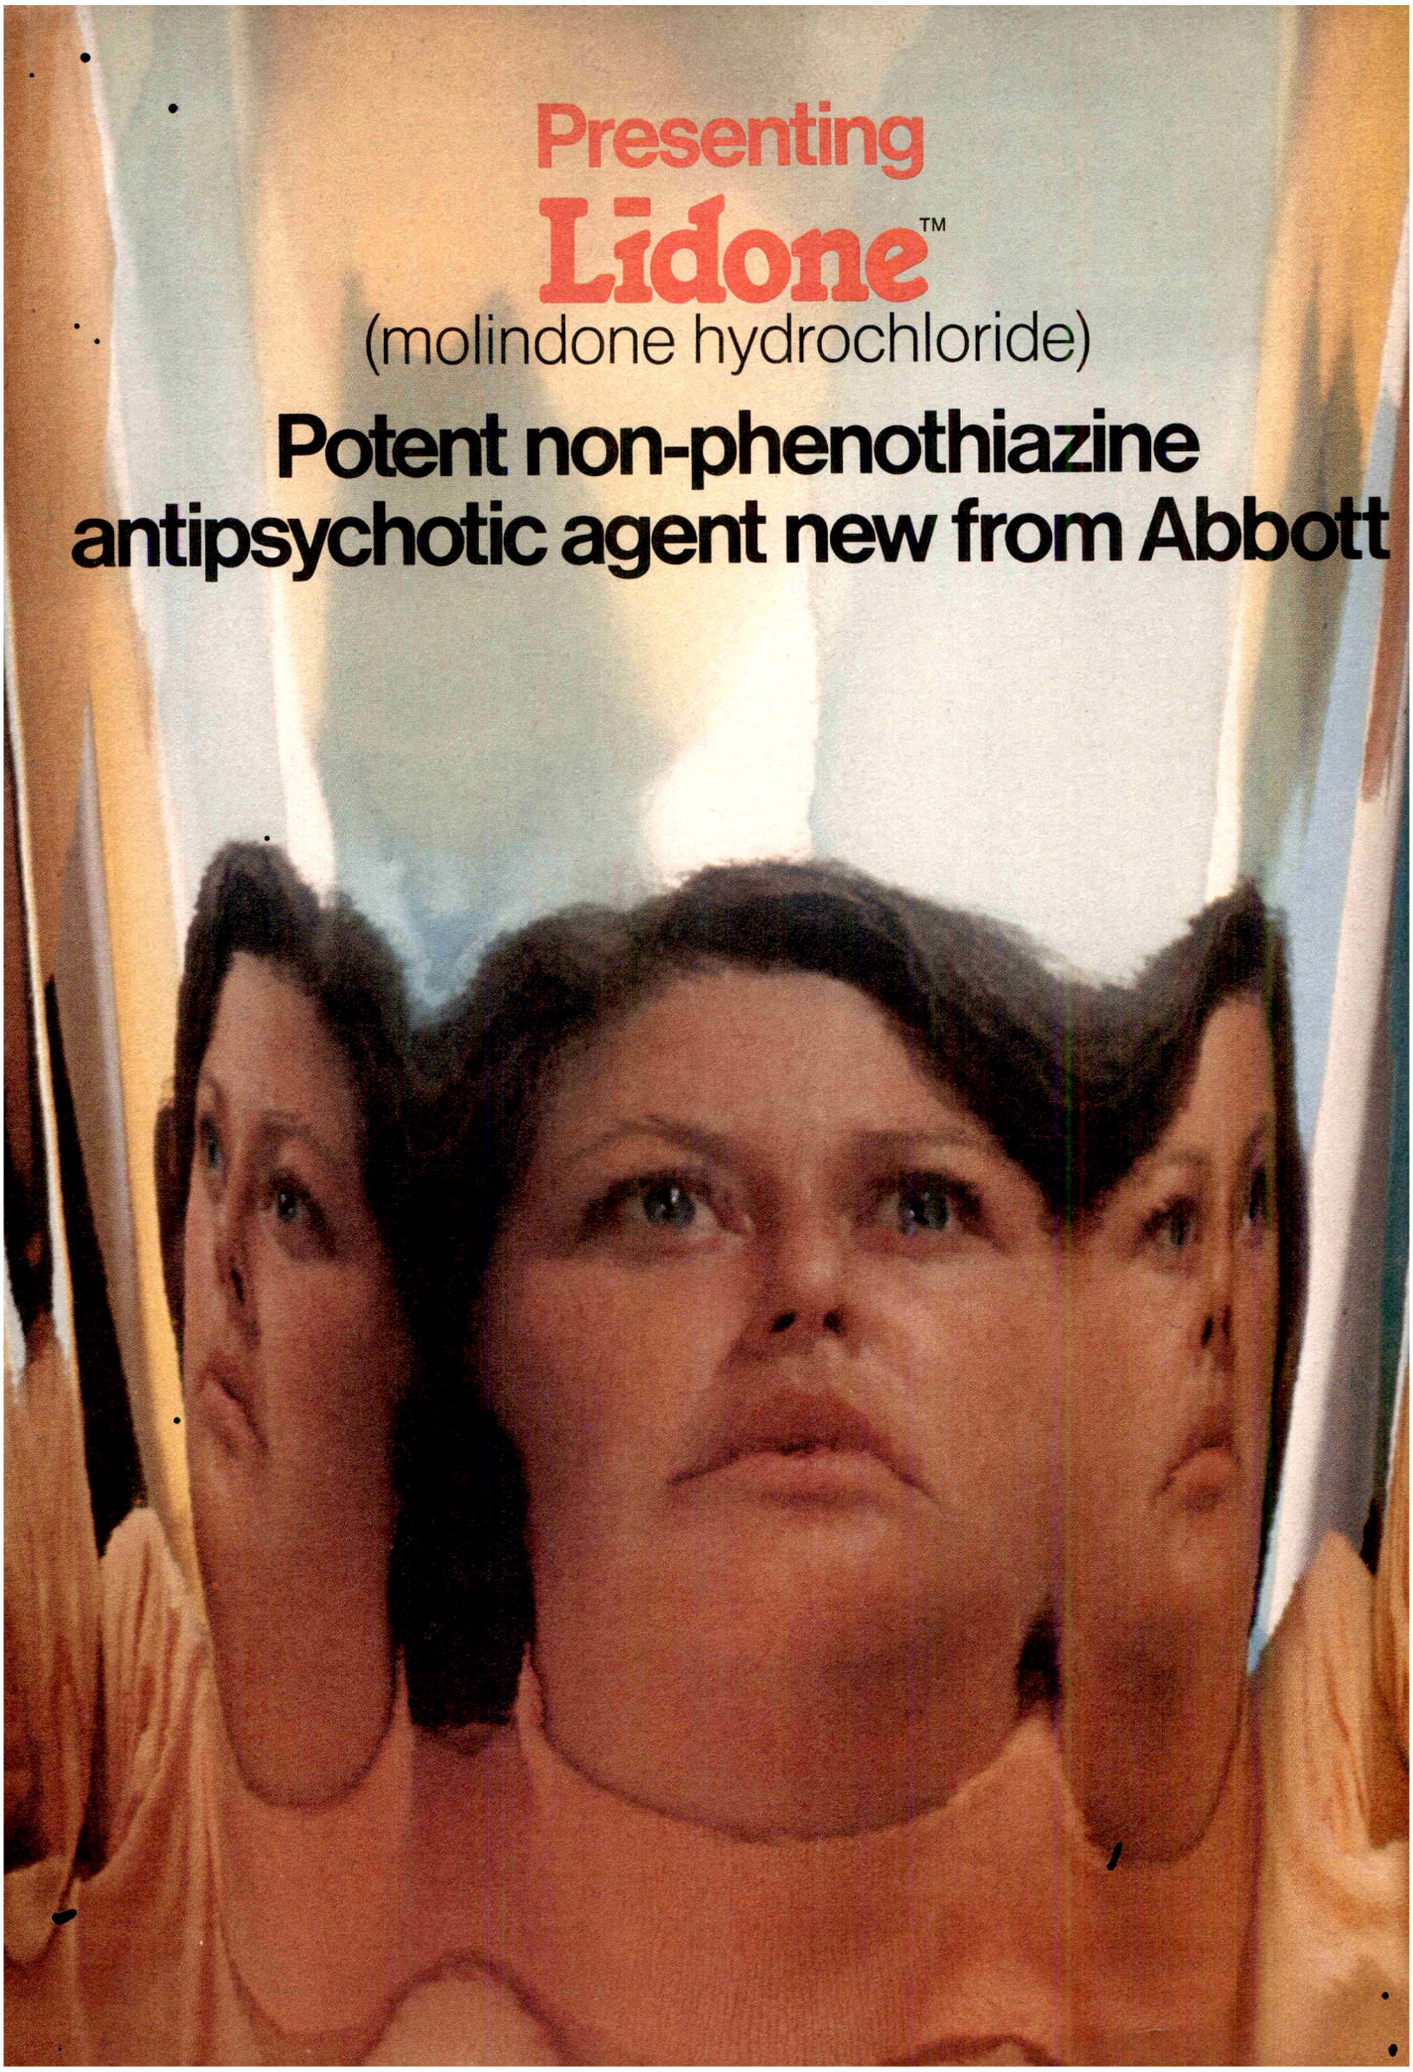
In order to tailor the regimen to the patient's response, flexibility in prescribing is essential. Through individualizing your patient's dosage of Librium, you can provide maximum beneficial calming effects with minimal side effects (the most common are dose-related and thus largely avoidable).

Moreover, Librium infrequently interferes with mental acuity. However, as with all CNS-acting drugs, patients should be cautioned against driving and hazardous activities requiring complete mental alertness.

With Librium you can rely on specific antianxiety action, probably confirmed by your own experience.

THAT'S WHAT MAKES LIBRIUM® LIBRIUM®

IV



chlordiazepoxide HCl/Roche

THE ANXIETY-SPECIFIC

ROCHE

Please see summary of product information on opposite page.

Presenting
Lidone™
(molindone hydrochloride)
Potent non-phenothiazine
antipsychotic agent new from Abbott

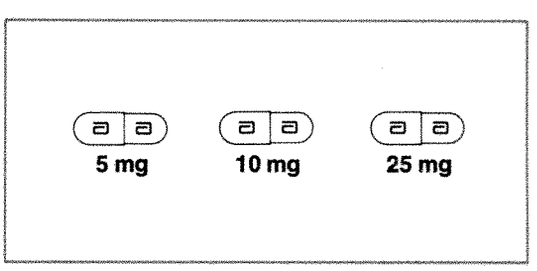
(molindone hydrochloride)

Lidone™ treats the psychosis with little likelihood of causing excessive weight gain or problem sedation

Lidone is molindone hydrochloride, a potent antipsychotic not related to other agents. It is effective against the manifestations of schizophrenia. Yet it is largely free of certain common problems.

Normalizing weight trend seen

Unlike some potent agents, Lidone has not caused excessive weight gain. Though both weight gain and loss have been seen, the shift has typically been toward normal or ideal weight.



Benefits in alertness

Lidone is classed among the "alerting" or less-sedating group of major tranquilizers. If drowsiness does occur during initial therapy, it is usually transient. Patients on continuing Lidone therapy tend to stay alert; hence they can be more responsive to rehabilitation measures.

Improved social outlook

Patients on Lidone have shown good progress in social competence and interest. And side effects such as sexual dysfunction or weight gain, which might disrupt family or interpersonal relationships, have not been reported.

Please contact your Abbott Representative to arrange for a clinical evaluation.

Lidone™ (molindone hydrochloride)

See overleaf for prescribing information.

7083207

Brief summary of
prescribing information for

Lidone™ (molindone hydrochloride)

DESCRIPTION — LIDONE (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

LIDONE is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4(5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

ACTIONS — LIDONE (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, LIDONE antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, LIDONE exerts its effect on the ascending reticular activating system.

Human metabolic studies show LIDONE (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24 to 36 hours. There are 36 recognized metabolites with less than 2% to 3% unmetabolized LIDONE being excreted in urine and feces.

INDICATIONS — LIDONE (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS — LIDONE (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose —
20 mg/kg/day — 2 weeks, no adverse effect
40 mg/kg/day — 2 weeks, no adverse effect

Pregnant Mice oral dose —
20 mg/kg/day — 9 days, slight increase resorptions
40 mg/kg/day — 9 days, slight increase resorptions

Pregnant Rabbits oral dose —
5 mg/kg/day — 12 days, no adverse effect
10 mg/kg/day — 12 days, no adverse effect
20 mg/kg/day — 12 days, no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of LIDONE (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of LIDONE (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS — Some patients receiving LIDONE (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving LIDONE. Caution should be exercised where increased activity may be harmful.

LIDONE does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, convulsive seizures have been reported in a few instances.

LIDONE has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS

CNS Effects — The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological Extrapyramidal Reactions — Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia — Motor restlessness may occur early.

Parkinson Syndrome — Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome — Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System — Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological — There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with LIDONE may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects — Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with LIDONE therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with LIDONE.

Cardiovascular — Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological — Lens opacities and pigmentary retinopathy have not been reported where patients have received LIDONE (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with LIDONE.

Skin — Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with LIDONE usage alone.

LIDONE (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when LIDONE is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia — Although rarely reported with LIDONE (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to greater in elderly patients on high-dose thera especially females. The symptoms are persiste and in some patients appear to be irreversible. T syndrome is characterized by rhythmical involu tary movements of the tongue, face, mouth or j (e.g., protrusion of tongue, puffing of chee puckering of mouth, chewing movements). The may be involuntary movements of extremities.

There is no known effective treatment of tardi dyskinesia; antiparkinsonism agents usually not alleviate the symptoms of this syndrome. It suggested that all antipsychotic agents be disc tinued if these symptoms appear. Should it be n essary to reinstitute treatment, or increase t dosage of the agent, or switch to a different an psychotic agent, the syndrome may be masked. has been reported that fine vermicular movemer of the tongue may be an early sign of the syndro and if the medication is stopped at that time t syndrome may not develop.

DOSAGE AND ADMINISTRATION — Initial a maintenance doses of LIDONE (molindone hyd chloride) should be individualized, and t minimal effective dose should be employed. Elde and debilitated patients should be started on low dosage.

DOSAGE SCHEDULE, BASED ON SEVERITY OF SYMPTOMATOLOGY

1. Mild — 5 mg three or four times a day; an crease to 15 mg three or four times a day may required.
2. Moderate — 10 mg three or four times a day; increase to 25 mg three or four times a day m be required.
3. Severe — daily dosage as high as 225 mg may required.

DRUG INTERACTIONS — Potentiation of dru administered concurrently with LIDONE (mol done hydrochloride) has not been reported. Ad tionally, animal studies have not shown increas toxicity when LIDONE is given concurrently w representative members of three classes of dru (i.e., barbiturates, chloral hydrate and antipark son drugs).

MANAGEMENT OF OVERDOSAGE — Symp matic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction absorption of LIDONE (molindone hydrochlori which is freely soluble in water.

Since the adsorption of LIDONE (molindone drochloride) by activated charcoal has not be determined, the use of this antidote must be c sidered of theoretical value.

Emesis in a comatose patient is contraindicat Additionally, while the emetic effect apomorphine is blocked by LIDONE in animals, t blocking effect has not been determined humans.

A significant increase in the rate of removal unmetabolized LIDONE from the body by for diuresis, peritoneal or renal dialysis would not expected. (Only 2% of a single ingested dose LIDONE is excreted unmetabolized in the urin However, poor response of the patient may jus use of these procedures.

While the use of laxatives or enemas might based on general principles, the amount of metabolized LIDONE in feces is less than 1%. trapyramidal symptoms have responded to the of diphenhydramine (Benadryl*) and the s thetic anticholinergic antiparkinson agents (Artane*, Cogentin*, Akineton*).

HOW SUPPLIED — LIDONE (molindone drochloride) capsules are supplied in bottles of in the following dosage strengths and colors:

5 mg (NDC 0074-5542-13) blue and cream
10 mg (NDC 0074-5543-13) red and cream
25 mg (NDC 0074-5544-13) brown and cream.

TM — Trademark
*Benadryl — Trademark, Parke Davis and Co.
*Artane — Trademark, Lederle Laboratories
*Cogentin — Trademark, Merck Sharp & Dohme
*Akineton — Trademark, Knoll Pharmaceutical Co.

NOW FROM SANDOZ

For the treatment of depression

PAMELOR®

(nortriptyline HCl) NF

25mg. Capsules

Provides 2 important benefits for both patients and clinicians.

- PAMELOR® begins to improve sleep patterns within a week.
- PAMELOR® allows patients to remain calm yet alert.

For Brief Summary please see following page.

NOW FROM SANDOZ

PAMELOR®
(nortriptyline HCl) NF
25 mg. Capsules

The antidepressant with 2 important clinical benefits

PAMELOR® begins to improve sleep patterns within a week

● PAMELOR® helps relieve the sleep problems that accompany depression: difficulty in falling asleep, restless sleep, and early-morning awakening. An improved pattern of sleep begins to appear in some patients within the first week of therapy.

● Overall improvement is often observed by the end of the second week. Maximum improvement with Pamelor®, as with other antidepressants, may require a longer period of therapy, particularly in severe depressive illnesses.

PAMELOR® allows patients to remain calm yet alert

● Helps improve depressed mood with a low level of stimulatory effect.

● PAMELOR® also has a mild calming action to help relieve the anxiety and tension that are often symptoms of depression. Because PAMELOR® rarely causes excessive drowsiness, patients are more alert and better able to function. Nevertheless, they should be cautioned about driving or operating machinery.

Indications: For relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Hypersensitivity. Should not be given concomitantly with MAO inhibitors or within 2 weeks of the use of this drug since hyperpyretic crises, severe convulsions, and fatalities have occurred when similar tricyclic antidepressants were used in such combinations. Cross-sensitivity with other dibenzazepines is a possibility. Contraindicated during acute recovery period after myocardial infarction.

Warnings: Use with caution in patients with cardiovascular disease because of tendency to produce sinus tachycardia and prolong conduction time. Myocardial infarction, arrhythmia, and strokes have occurred. May block antihypertensive action of guanethidine and similar agents. Because of anticholinergic activity, use cautiously in patients with glaucoma or a history of urinary retention. Patients with a history of seizures should be followed closely because the drug is known to lower the convulsive threshold. Great care is required for hyperthyroid patients and those taking thyroid medication because of possible development of cardiac arrhythmia. Caution patients about possibility of impaired mental and/or physical ability to operate a motor vehicle or dangerous machinery. Response to alcoholic beverages may be exaggerated and may lead to suicidal attempts. Safe use during pregnancy, lactation, and women of childbearing potential has not been established and the drug should not be given unless clinical situation warrants potential risk. Not recommended for use in children.

Precautions: Psychotic symptoms may be exacerbated in schizophrenic patients. Increased anxiety and agitation may occur in overactive or agitated patients. Manic-depressive patients may experience shift to manic phase. Hostility may be aroused. Concomitant administration of reserpine may produce a "stimulating" effect. Watch for possible epileptiform seizures during treatment. Use cautiously with anticholinergic or sympathomimetic drugs. Concurrent electroconvulsive therapy may increase hazards associated with nortriptyline HCl. When possible, discontinue drug several days prior to surgery. Potentially suicidal patients require supervision and protective measures during therapy. Prescriptions should be limited to the least possible quantity. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: The pharmacologic similarities among the tricyclic antidepressant drugs require that each of the following reactions be considered when nortriptyline is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia, panic, nightmares; hypomania; exacerbation of psychosis.

Neurologic: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alteration in EEG patterns; tinnitus.

Anticholinergic: Dry mouth and rarely, associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue), drug fever, cross-sensitivity with other tricyclic drugs.

Hematologic: Bone-marrow depression, including agranulocytosis; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black-tongue.

Endocrine: Gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness, fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though these are not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Dosage and Administration: *Usual adult dose*—25 mg. three or four times daily; dosage should begin at a low level and increase as required. *Elderly and Adolescent:* 30 to 50 mg. per day, in divided doses. Doses above 100 mg. per day and use in children are not recommended. If a patient develops minor side effects, the dosage should be reduced. The drug should be discontinued promptly if adverse effects of a serious nature or allergic manifestations occur.

How Supplied: Capsules 10 mg. and 25 mg.; solution 10 mg./5 cc.

For more detailed information see full prescribing information.

a valuable link to the resources of the American Psychiatric Association

for institutions and agencies concerned with the care of the mentally disabled

Enrollment in the Hospital & Community Psychiatry Service brings multiple copies of *Hospital & Community Psychiatry* into member agencies every month, keeping staff up to date on developments and issues in the mental health field, offering new ideas and fresh perspectives, and serving as a useful resource in staff development and training programs.

Hospital & Community Psychiatry is just one of the benefits of membership in the H&CP Service. Others include a film library containing more than a hundred films specially chosen for their usefulness in staff development and community education programs; supplementary mailings of important books, reports, articles, or other material of special interest to administrators or clinicians; reduced registration fees at the annual fall Institute on Hospital & Community Psychiatry; and, on request, information and consultation from the professional staff of the American Psychiatric Association. The H&CP Service also sponsors the annual Achievement Awards competition, which gives special recognition to outstanding programs for the mentally ill and mentally retarded.

Please send me information about membership in the Hospital & Community Psychiatry Service.

From the Sleep Research Laborator

Dalmane® (flurazepam HC proved the most effective hypnotic over 14 nights...[1]

For those patients who need it, Dalmane (flurazepam HCl) alone provides continued effectiveness[2,3]

Since insomnia is often transient and intermittent, the prolonged administration of a hypnotic is generally not necessary or recommended. But for those patients whose insomnia is a chronic problem, the continued effectiveness of Dalmane is a decided benefit. Even at the end of a 28-night medication period, patients with chronic insomnia were falling asleep faster, spending less time awake during the night, and sleeping substantially longer on Dalmane 30 mg *h.s.* than on baseline placebo nights (average results). This effectiveness was proved[2] and confirmed[3] in two independent sleep research studies using a new 47-night protocol. When similarly evaluated, pentobarbital was ineffective at the end of two weeks.[2]

14 consecutive nights:
3 in sleep laboratory, 8 at home,
3 in sleep laboratory

..and now, the only one proved effective over 28 nights.[2,3]

n previous studies,[1] hloral hydrate and glutethimide ost most or all effectiveness

ı fact, continued effectiveness for both inducing and maintain-ıg sleep over 14 consecutive nights[1] has long been an exclusive enefit of Dalmane. No other available sleep agent, including ıloral hydrate or glutethimide,[1] has been able to demonstrate ıch effectiveness in the sleep research laboratory.

.he safety record of)almane (flurazepam HCl) is well stablished

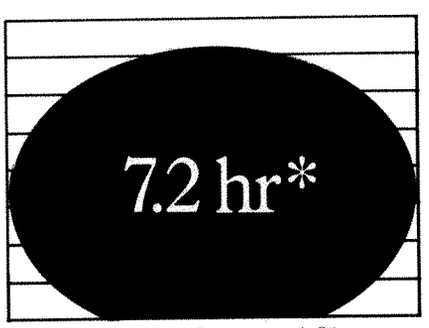
almane is relatively safe and well tolerated. Prolonged dministration is not generally necessary, but if used repeatedly, eriodic blood counts and liver and kidney function tests ıould be performed.

Dalmane®
(flurazepam HCl)

relatively safe...
no need
to increase
dosage

ROCHE

28 consecutive nights:
3 in sleep laboratory, 7 at home,
4 in sleep laboratory, 10 at home,
4 in sleep laboratory[3]



Please see following page for a summary of product information.

1,5,7,14,28 nights... as needed, the effectiveness of **Dalmane**® one *h.s.* (flurazepam HCl) C IV meets the challenge of insomnia

One 30-mg capsule *h.s.*—usual adult dosage (15 mg may suffice in some patients).
One 15-mg capsule *h.s.*—initial dosage for elderly or debilitated patients.

- **Patients fall asleep rapidly, sleep longer on a single *h.s.* dose**
- **Nighttime awakenings and time spent awake are reduced**
- **Effectiveness maintained without dosage increase from night to night**
- **Patients generally awaken refreshed; morning "hangover" is infrequent**

TOTAL SLEEP TIME (OVERALL MEAN)[3]
(5 patients with insomnia)

Dalmane (flurazepam HCl)
nights 1-3, 12-14, 26-28

*Significantly increased over baseline placebo ($p < .05$).

1. Kales A, *et al*: *Arch Gen Psychiatry* 23:226-232, Sep 1970
2. Kales A, *et al*: *Clin Pharmacol Ther* 18:356-363, Sep 1975
3. Dement WC, *et al*: Long-term effectiveness of flurazepam 30 mg *h.s.* on chronic insomniacs. Presented at the 15th annual meeting of the Association for Psychophysiological Study of Sleep, Edinburgh, Scotland, Jun 30-Jul 4, 1975

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).
***Usage in Pregnancy:* Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane (flurazepam HCl), a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit initial dosage to 15 mg to preclude oversedation, dizziness and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

Coverage and Utilization of Care for Mental Conditions Under Health Insurance —Various Studies, 1973–74

By Louis S. Reed, Ph.D.
Consultant in Health Economics, American Psychiatric Association

This book reports six studies that add to the growing body of data demonstrating the feasibility of covering mental illness under health insurance. Although in some ways it may be considered a supplement to APA's 1972 book **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (Reed, Myers, and Scheidemandel), all of the data are new. The studies cover the following areas:

- Utilization of mental benefits under the Blue Cross and Blue Shield plan for federal employees, documenting that a "plateau" in the use of these benefits was reached in 1973–74.
- Comparison of benefits for mental and other illnesses under selected employee health benefit plans.
- Coverage of mental illness under collective bargaining agreements of selected unions.
- Utilization of care for mental conditions under the Canadian health insurance program, which gives the same coverage for mental as for other conditions.
- Updating of information on Blue Cross benefits for hospital care of mental illness.
- Data from selected Blue Cross and Blue Shield plans on coverage and utilization of mental conditions, with emphasis on major medical coverage.

80pp. Paperbound

Single copy, $4.00; 10–49 copies; $3.80 each; 50 or more copies, $3.20 each.

SPECIAL OFFER: One copy of this book (regular price, $4.00) and one copy of **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (regular price, $6.50) for $8.50.

Amphetamines work in MBD.
Methylphenidate works in MBD.

Then why Cylert® for MBD?

(pemoline)

Because Cylert offers a lot:

- Once-a-day dosage at home
- Elimination of mid-day school dose and need for school personnel supervision
- Avoids ups and downs of drug action brought about by multiple daily dosage
- Control of medication by the parent
- A chewable dosage form
- Less physician paper work (Cylert is in schedule IV)
- Safety and efficacy proven in extensive clinical studies*

*Copy of the Cylert Monograph available to Physicians on written request.

Dosage and administration

Cylert is administered as a single oral dose each morning.

The recommended starting dose is 37.5 mg/day. This daily dose should be gradually increased by 18.75 mg at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with Cylert is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration. Drug administration should be interrupted occasionally (once or twice a year) to determine if behavioral symptoms are sufficient to require continued therapy.

When not to use medication

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

ABBOTT

Please see next page for Prescribing Information.

7083202 R1

Cylert and Cylert Chewable Tablets

(pemoline)

Prescribing Information

Description: Cylert (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

Cylert (pemoline) is supplied as tablets for oral administration.

Clinical Pharmacology: Cylert (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. Cylert is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

Cylert (pemoline) has a gradual onset of action in children with minimal brain dysfunction. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

Indications: *MINIMAL BRAIN DYSFUNCTION IN CHILDREN*—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: The cause of minimal brain dysfunction (MBD) is unknown. Diagnosis of MBD involves the use of medical, psychological, educational, and social tools, since no single diagnostic test is adequate.

MBD is characterized by chronic moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindications: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

Warnings: Cylert is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Sufficient data on the safety and the efficacy of the long-term use of Cylert in children with minimal brain dysfunction are not yet available.

A temporary suppression of the predicted growth rate (weight and/or height gain) has been reported for children receiving long-term stimulant therapy. A definite causal relationship between stimulant drugs and this finding has not been established.

Precautions: Liver function tests should be performed periodically during therapy with Cylert. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

Cylert should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of Cylert with other drugs has not been studied in humans. Patients who are receiving Cylert concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

Cylert failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with Cylert. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. Cylert should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of Cylert (pemoline) for use during pregnancy and lactation has not been established.

Fertility, reproduction, and teratology studies were conducted in laboratory animals. Pemoline, in doses of 18.75 or 37.5 mg./kg./day, had no effect on the fertility of male or female rats. The drug, when given to pregnant rats (from gestation day 15 through weaning) and to rabbits (from gestation days 6-18) at these same dosage levels, produced no teratogenic or embryotoxic effects, and had no effect on the viability of the young at birth. However, increased incidences of stillbirths and cannabilization were observed when pemoline was given to rats at these dosage levels, beginning 14 days prior to conception.

Adverse Reactions: Insomnia is the most frequently reported side effect of Cylert; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking Cylert, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking Cylert; a causal relationship between the drug and this clinical finding has not been established.

There have been reports of dyskinetic movements of the lips, face, and extremities occurring with the use of Cylert. Convulsive seizures have also been reported. A definite causal relationship between Cylert and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with Cylert often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

Overdosage: Signs and symptoms of acute Cylert overdosage may include agitation, restlessness, hallucinations, tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of preliminary studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of Cylert overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

Dosage and Administration: Cylert (pemoline) is administered as a single oral dose each morning.

The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with Cylert is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration. Drug administration should be interrupted occasionally (once or twice a year) to determine if behavioral symptoms are sufficient to require continued therapy.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (yellow-colored) in bottles of 100 (NDC 0074-6025-13)

37.5 mg. tablets (orange-colored) in bottles of 100 (NDC 0074-6057-13)

75 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-6073-13)

Cylert Chewable is supplied as monogrammed, grooved tablets in one dosage strength:

37.5 mg. tablets (orange-colored) in bottles of 100 (NDC 0074-6088-13)

A Timely New Book from The Joint Information Service

This latest Joint Information Service field study provides a concise, comprehensive overview of the complex matter of the very young American child and his mental health, and then describes in intimate detail seven unique programs for pre-school children with problems—from North Hollywood's Dubnoff Center, emphasizing education as its primary therapeutic modality, to Baltimore's Martin Luther King, Jr. Parent-Child Center, serving two housing projects, served by Johns Hopkins, and largely governed by its own people. All different in treatment approach and philosophy, the programs described are uniform in their dedication to innovation in improving service to the emotionally disturbed very young child, and, equally, to the emotional well being of all young children.

This thoughtful and perceptive description of what has been created by some of the best informed, most experienced and thoughtful specialists in mental health services for very young children should be welcome to all involved in the mental health of children and a casebook for those dealing with child and family mental health.

An articulate exposition of the immense problems and encouraging accomplishments in a particularly difficult area of endeavor . . . . Beyond their concern with the manifestly ill child, the authors intriguingly explore what may be needed to enhance the mental good health of all young children . . . . A significant contribution.

James N. Sussex, M.D.

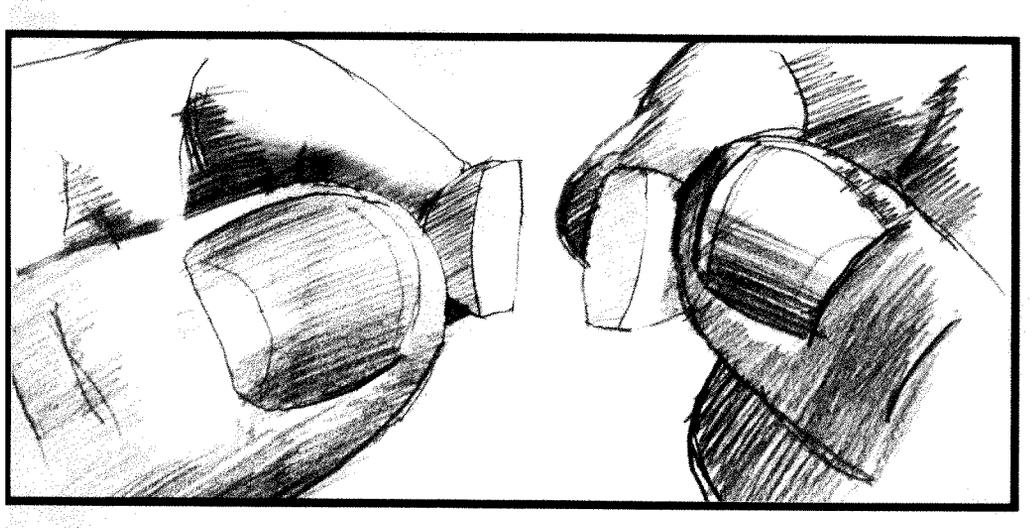
Why Endep® makes
with amitriptyline HC

Scored tablets h.s. enhance compliance and tolerability

Once you select the appropriate maintenance dose, you can prescribe a single tablet of Endep h.s. secure in the knowledge that you can adjust the dose by a half tablet without requiring the patient to obtain a new Rx. The simplicity of this h.s. schedule not only encourages compliance, but lessens the likelihood of anticholinergic and sedative side effects during daytime.

Scored tablets h.s. reduce confusion



Bedtime dosage means that the patient has only one dose of Endep to remember, thus minimizing possible confusion with other medications taken concomitantly. The built-in flexibility of the scored tablet permits half-strength dosage adjustments without confusing the patient with a new color or size of medication.

ROCHE

ong-term maintenance nore practical:

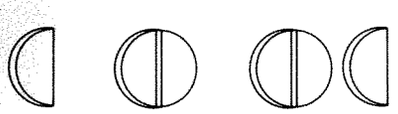
Scored tablets h.s. promote economy

The economy of Endep (amitriptyline HCl) is particularly evident during long-term maintenance therapy, when your patient is purchasing refills of the single strength you have prescribed. The h.s. schedule enables you to prescribe a single strength in place of a more expensive multiple-dose prescription. The scored tablet permits you to adjust the regimen without putting the patient through the expense of a new prescription fee, without wasting tablets and without necessitating the purchase of more costly multiple-dose refills.

Endep®

amitriptyline HCl / Roche

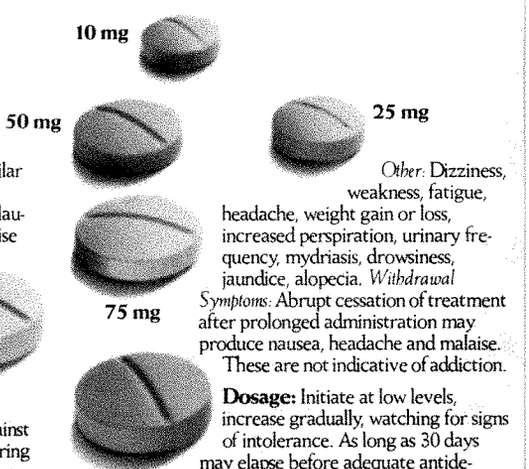
The half-strength advantage



Before prescribing, please see following page for a summary of product information.

Practicality is a fundamental fact about Endep®

amitriptyline HCl/Roche



Every tablet of Endep (amitriptyline HCl) is scored for precise, convenient adjustment of dosage.

Half-tablet adjustment of dosage does not require a new Rx.

Single daily *h.s.* dosage promotes compliance and economy.

Compliance with practical regimen promotes optimal response.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle-closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels, increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier.

Initial Adult Dosage: Outpatients—25 mg *t.i.d.*; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate—50 to 100 mg *h.s.*, gradually increasing *h.s.* dose up to 150 mg/day. Hospitalized Patients—Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day.

Adolescent and Elderly Patients: In general, 10 mg *t.i.d.* with 20 mg *h.s.* may be satisfactory for those who do not tolerate higher doses.

Maintenance Dosage: With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg *b.i.d.* to *q.i.d.*, or 10 mg *q.i.d.* Continue maintenance therapy 3 months or longer to avoid relapse.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg, 75-mg, 100-mg and 150-mg scored tablets—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg, 100 mg and 150 mg), available singly and in trays of 10.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depression) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

"I'm just a shadow of what I used to be."

That is what depressed individuals may feel is the substance of their being. There is no pleasure, no joy – nothing grows – and in the cold shadow of depression their activities are inhibited, while initiative may be eroded or destroyed. The tragedy is that they can see that others are able to live on the brighter side but they, themselves, cannot reach it on their own.

Your experience in treating depression, and Tofranil-**PM** can help light the way.

Tofranil-**PM**®
imipramine **pamoate**

Geigy

Unsurpassed effectiveness among tricyclics in relieving symptoms of anxious depression.

Before prescribing Tofranil-PM, please review a summary of the prescribing information on the back of this page.

Tofranil-PM®
imipramine pamoate

Geigy

As anxiety, agitation, sleep disturbances, and other depressive symptoms are relieved, mood and motivation may be markedly improved.

Patients are usually alert and capable of functioning at more normal levels of behavior.

Tofranil-PM encourages patient compliance because one capsule lasts from bedtime to bedtime.

Good results are usually seen at the starting dose of one 75-mg capsule h.s.

For many patients, dosage can be safely increased to 150 mg daily.

As with all tricyclics, sedation may occur. Please caution patients against driving or operating dangerous machinery.

Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Tofranil-PM®
brand of imipramine pamoate

Indications: For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications: The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

—patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
—patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
—hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
—patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
—patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as operating an automobile or machinery, the patient should be cautioned accordingly.

Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Adverse Reactions: Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: In adult outpatients, therapy should be initiated on a once-a-day basis with 75 mg./day. This may be increased to 150 mg./day which is the dose level which usually obtains optimum response. If necessary, dosage may be increased to 200 mg./day. Dosage should be modified as necessary by clinical response and any evidence of intolerance. Daily dosage may be given at bedtime, or in some patients in divided daily doses.

Hospitalized patients should be started on a once-a-day basis with 100-150 mg./day and may be increased to 200 mg./day. Dosage should be increased to 250-300 mg./day if there is no response after two weeks.

Following remission, maintenance medication may be required for a longer period of time at the lowest dose that will maintain remission. The usual adult maintenance dosage is 75-150 mg./day on a once-a-day basis, preferably at bedtime.

In adolescent and geriatric patients, capsules of Tofranil-PM, brand of imipramine pamoate, may be used when total daily dosage is established at 75 mg. or higher. It is generally unnecessary to exceed 100 mg./day in these patients. This dosage may be given once a day at bedtime or, if needed, in divided daily doses.

How Supplied: Tofranil-PM, brand of imipramine pamoate: Capsules of 75, 100, 125 and 150 mg. (Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg. of imipramine hydrochloride.)

Tranxene® CV CAPSULES SINGLE DOSE TABLETS

CLORAZEPATE DIPOTASSIUM 4306CB **Brief Summary**

ACTIONS—Pharmacologically, TRANXENE (clorazepate dipotassium) has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine.

INDICATIONS—TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE for long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS—TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS—TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS—In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS—The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION—

For symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg TRANXENE initially, followed by 30 to 60 mg in divided doses; 2nd 24 hours, 45 to 90 mg in divided doses; 3rd 24 hours, 22.5 to 45 mg in divided doses; 4th day, 15 to 30 mg in divided doses. Thereafter gradually reduce to 7.5 to 15 mg daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS—If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE (clorazepate dipotassium) is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE—Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed, since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY—Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

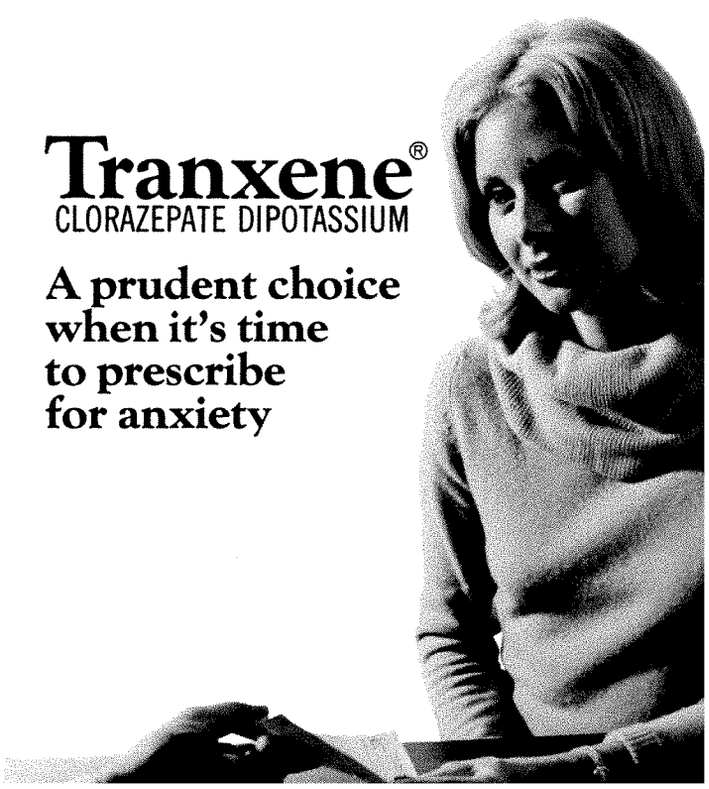
Absorption–Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED—TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3418-11).



15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 100 (NDC 0074-2699-13).

7043191/R

A prudent prescription for today's anxious patient

A different tranquilizer. Times change. Today's patient has changed. And the physician's most prudent choice of therapy for anxious patients may also change. Thus if you are now thinking about changing your choice of minor tranquilizers, consider Tranxene.

A change of look. Tranxene is a physically distinctive change of therapy. It's very different in form and appearance from any other tranquilizers your patients have previously received or seen.

Greater versatility. Its added dosage options are different too. They permit not only conventional divided doses, but also convenient once-a-day regimens . . . including an ultrasimple single dose tablet (11.25 mg) especially suited to elderly patients.

Yet the same effectiveness. Prescribe with confidence. In numerous published studies involving hundreds of patients, Tranxene has been shown to be clinically equivalent to diazepam in treating anxiety.

Tranxene® 4306CB C IV

CLORAZEPATE DIPOTASSIUM

REMOVE THE MASK OF SCHIZOPHRENIC SYMPTOMS

'STELAZINE' PROVIDES EFFECTIVE CONTROL OF HALLUCINATIONS, DELUSIONS, ANXIETY, AGITATION AND OTHER SCHIZOPHRENIC SYMPTOMS.

A FIRST CHOICE FOR THERAPY, 'STELAZINE' ALSO APPEARS TO HAVE AN ACTIVATING EFFECT WHICH IS ESPECIALLY USEFUL IN WITHDRAWN, APATHETIC OR DETACHED PATIENTS.

- EFFECTIVELY CONTROLS PSYCHOTIC SYMPTOMS
- SELDOM CAUSES EXCESSIVE SEDATION
- CONVENIENT B.I.D. DOSAGE

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudoparkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit 3 copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later. Annual meeting papers should not be submitted to the *Journal* until *after* the annual meeting.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

All communications about a manuscript should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; with other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, the copyright of all parts of the paper, including any illustrations, passes from the author to the *Journal*. Written permission to reprint material published in the *Journal* must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for this permission.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

SPECIFICATIONS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond paper. **All parts of the manuscript** (including case reports, footnotes, references, etc.) **should be double spaced,** with margins of 2½-3¾ cm (1-1½ inches) at the top, bottom, and both sides. Subheads should be inserted at reasonable intervals. All abbreviations should be explained. All measurements must be in metric units.

Length. All pages of the manuscript must be numbered, including references, tables, and figures. The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles: 3,800 words or the equivalent including references, tables, and figures (about 15 manuscript pages). Brief Communications: 2,500 words or the equivalent (about 10 manuscript pages); see stipulations above. Clinical and Research Reports: 1,000 words, 10 references, 1 table. Letters to the Editor: 500 words, 5 references. Please write the total number of words and the number of tables and figures on the title page of the submitted material.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the coauthor who has been designated to assume responsibility for the paper and reprint requests. Authors named in the by-line should be limited to principal researchers and writers; other collaborators may be acknowledged in a footnote.

Precis. A brief precis (60–100 words for regular articles, 40–60 words for Brief Communications) is included at the beginning of each article. The author may prepare the precis or ask that the *Journal* staff prepare it.

References. References should be typed **double spaced** on a separate sheet of paper. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P: New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Tables and figures should be self-explanatory and should supplement, not duplicate, text. See recent issues of the *Journal* for general style.

Each table should be typed double spaced on a separate sheet attached at the end of the manuscript. Columns of like material should read down, not across.

One complete set of figures, in the form of glossy prints, should be submitted. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Graphs should be finished drawings not requiring further artwork. Authors are urged to engage professional assistance in the preparation of figures and may be charged for any further artwork that must be done in the editorial office.

AUTHOR CORRECTIONS

After the paper has been scheduled for publication, the edited manuscript will be sent to the first-named author for corrections and answers to queries. Prompt return is necessary. If an author expects to be away from his office for a long period of time after being notified of the acceptance of his paper, he should inform the *Journal* office or arrange with a coauthor to assume responsibility for the paper. Galley proofs will not be sent to authors.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Requests from others to order reprints should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

Hallucinations and delusions rapidly controlled

Trapped by unrealistic perceptions...

...and terrified by his hallucinations and delusions on admission. Because Navane (thiothixene) is particularly effective in controlling these symptoms and their resulting suspiciousness and anxiety, it can provide the essential first step toward restoring stabilization and facilitating the development of purposeful activity. Extensive clinical data and widespread experience confirm the effectiveness of Navane in rapidly controlling such typical psychotic behavior on admission.

Long-term therapy is facilitated...

...because Navane offers an unsurpassed safety record among effective neuroleptic agents, permitting continuing control of symptoms of psychoses such as hallucinations and delusions. Like other antipsychotic agents, extrapyramidal symptoms may occur, but are readily controlled through dosage adjustments or antiparkinsonian agents. Cardiovascular effects such as hypotension, and hepatic or hematopoietic effects rarely occur and are generally mild and transient, with no jaundice or agranulocytosis reported to date.

An effective first step towards discharge...

Navane®

(thiothixene) (thiothixene HCl)

Capsules 1 mg., 2 mg., 5 mg., 10 mg., 20 mg. Concentrate 5 mg./ml.—Intramuscular 2 mg./ml.

New York, New York 10017

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg
(thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children–The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate–In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor elevating action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg, of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

MONTEFIORE HOSPITAL AND MEDICAL CENTER

The Department of Psychiatry
Department of Psychiatry, Albert Einstein College of Medicine
offers

FELLOWSHIPS

in

POST-DOCTORAL RESEARCH TRAINING

Fellowship positions are available through N.I.M.H.-supported programs that provide basic preparation for research in areas relevant to mental health, the brain and behavior. The program is available to persons who have completed three years of residency training in psychiatry or the requirements for the Ph.D. in a behavioral or social science.

Emphasis is on acquiring proficiency in the fundamental principles of research strategy, methodology and techniques currently employed in laboratory and clinical studies in psychiatry. The traineeships stress active participation in research work under the supervision of faculty preceptors, supplemented by a curriculum of seminars and workshops.

Appointments are full-time and are for one to two years.

Culture, Medicine and Psychiatry

An International Journal of Comparative Cross-Cultural Research

Editor in Chief:
Arthur M. Kleinman, M.D., M.A.

Culture, Medicine and Psychiatry covers three closely-related fields for which there is at present no single, integrated, interdisciplinary forum:

- medical and psychiatric anthropology,
- cross-cultural psychiatry,
- cross-societal clinical and epidemiological studies.

Exploring the border between anthropology and clinical medicine, it focuses on the cultural context of illness (biomedical and psychological), health care relationships, and healing. It will also explore various facets of the common ground between anthropology and psychiatry.

Among the articles already published in **Culture, Medicine and Psychiatry** are:

LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

A CONSISTENT PATTERN OF PATIENT RESPONSE

Because psychotherapy holds so many variables, predictability of patient response to adjunctively administered medications is a much-sought objective. The consistency of patient response to Librium® (chlordiazepoxide HCl) therefore makes it a good choice when clinically significant anxiety interferes with therapy.

In order to tailor the regimen to the patient's response, flexibility in prescribing is essential. Through individualizing your patient's dosage of Librium, you can provide maximum beneficial calming effects with minimal side effects (the most common are dose-related and thus largely avoidable).

Moreover, Librium infrequently interferes with mental acuity. However, as with all CNS-acting drugs, patients should be cautioned against driving and hazardous activities requiring complete mental alertness.

With Librium you can rely on specific antianxiety action, probably confirmed by your own experience.

THAT'S WHAT MAKES LIBRIUM® LIBRIUM®

chlordiazepoxide HCl/Roche

Personality and Adjustment in the Aged

By R. D. SAVAGE, L. B. GABER, P. G. BRITTON, N. BOLTON and A. COOPER

Research carried out over a ten-year period by a group based at the University of Newcastle-upon-Tyne is comprehensively covered in this book, which not only presents interesting and formerly unpublished information concerning personality structure and its assessment in the aged, but also reviews previous work in this area.

The investigations are particularly concerned with the assessment of normal personality characteristics in both normal and psychiatric patient populations, using in this context the personality theory and measurement techniques of Cattell and Eysenck. Psychopathology is studied in terms of the Minnesota Multiphasic Personality Inventory diagnoses, and self-concept and adjustment are measured using the methods of Fitts, Havighurst and Cavan. Finally, the authors propose a theoretical model of personality types and their adjustment amongst the aged and discuss its implications.

NANCY FREY

NOW FROM SANDOZ

For the treatment of depression

PAMELOR®

(nortriptyline HCl) NF

25mg. Capsules

Provides 2 important benefits for both patients and clinicians.

- PAMELOR® begins to improve sleep patterns within a week.
- PAMELOR® allows patients to remain calm yet alert.

For Brief Summary please see following page.

NOW FROM SANDOZ

PAMELOR®
(nortriptyline HCl) NF
25 mg. Capsules

The antidepressant with 2 important clinical benefits

PAMELOR® begins to improve sleep patterns within a week

● PAMELOR® helps relieve the sleep problems that accompany depression: difficulty in falling asleep, restless sleep, and early-morning awakening. An improved pattern of sleep begins to appear in some patients within the first week of therapy.

● Overall improvement is often observed by the end of the second week. Maximum improvement with Pamelor®, as with other antidepressants, may require a longer period of therapy, particularly in severe depressive illnesses.

PAMELOR® allows patients to remain calm yet alert

● Helps improve depressed mood with a low level of stimulatory effect.

● PAMELOR® also has a mild calming action to help relieve the anxiety and tension that are often symptoms of depression. Because PAMELOR® rarely causes excessive drowsiness, patients are more alert and better able to function. Nevertheless, they should be cautioned about driving or operating machinery.

Indications: For relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Hypersensitivity. Should not be given concomitantly with MAO inhibitors or within 2 weeks of the use of this drug since hyperpyretic crises, severe convulsions, and fatalities have occurred when similar tricyclic antidepressants were used in such combinations. Cross-sensitivity with other dibenzazepines is a possibility. Contraindicated during acute recovery period after myocardial infarction.

Warnings: Use with caution in patients with cardiovascular disease because of tendency to produce sinus tachycardia and prolong conduction time. Myocardial infarction, arrhythmia, and strokes have occurred. May block antihypertensive action of guanethidine and similar agents. Because of anticholinergic activity, use cautiously in patients with glaucoma or a history of urinary retention. Patients with a history of seizures should be followed closely because the drug is known to lower the convulsive threshold. Great care is required for hyperthyroid patients and those taking thyroid medication because of possible development of cardiac arrhythmia. Caution patients about possibility of impaired mental and/or physical ability to operate a motor vehicle or dangerous machinery. Response to alcoholic beverages may be exaggerated and may lead to suicidal attempts. Safe use during pregnancy, lactation, and women of childbearing potential has not been established and the drug should not be given unless clinical situation warrants potential risk. Not recommended for use in children.

Precautions: Psychotic symptoms may be exacerbated in schizophrenic patients. Increased anxiety and agitation may occur in overactive or agitated patients. Manic-depressive patients may experience shift to manic phase. Hostility may be aroused. Concomitant administration of reserpine may produce a "stimulating" effect. Watch for possible epileptiform seizures during treatment. Use cautiously with anticholinergic or sympathomimetic drugs. Concurrent electroconvulsive therapy may increase hazards associated with nortriptyline HCl. When possible, discontinue drug several days prior to surgery. Potentially suicidal patients require supervision and protective measures during therapy. Prescriptions should be limited to the least possible quantity. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: The pharmacologic similarities among the tricyclic antidepressant drugs require that each of the following reactions be considered when nortriptyline is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia, panic, nightmares; hypomania; exacerbation of psychosis.

Neurologic: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alteration in EEG patterns; tinnitus.

Anticholinergic: Dry mouth and rarely, associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue), drug fever, cross-sensitivity with other tricyclic drugs.

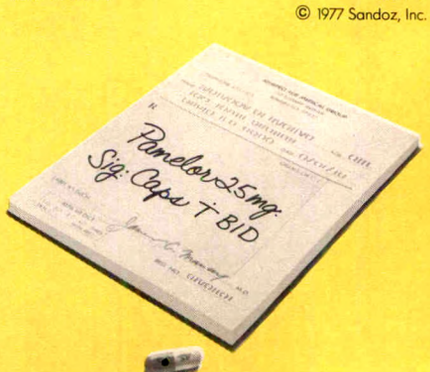
Hematologic: Bone-marrow depression, including agranulocytosis; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black-tongue.

Endocrine: Gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness, fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though these are not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.



Dosage and Administration: *Usual adult dose*—25 mg. three or four times daily; dosage should begin at a low level and increase as required. *Elderly and Adolescent:* 30 to 50 mg. per day, in divided doses. Doses above 100 mg. per day and use in children are not recommended. If a patient develops minor side effects, the dosage should be reduced. The drug should be discontinued promptly if adverse effects of a serious nature or allergic manifestations occur.

How Supplied: Capsules 10 mg. and 25 mg.; solution 10 mg./5 cc.

For more detailed information see full prescribing information.

SANDOZ EAST HANOVER, N.J. 07936

UNIQUE-NESS:

In People & at the Lutheran Hospital Psychiatric Care Unit

Providing complete psychiatric care in a general hospital setting with special emphasis on disorders of adolescence.

Lutheran Hospital of Milwaukee, Inc.

Basil Jackson, M.D., D.P.M., M.Th., D.Sc., F.A.C.P.
Chairman, Department of Psychiatry
2200 W. Kilbourn Ave., Milwaukee, WI. 53233

BASIC NEUROLOGY FOR PSYCHIATRISTS, GENERALISTS AND FAMILY PRACTITIONERS

Feb. 27-Mar. 3, 1978
Konover Hotel, Miami Beach, Florida

Sponsor: Department of Neurology, University of Miami School of Medicine. 32 hours Category 1. Designed primarily for Psychiatrists who are preparing for specialty board examinations, the course will also serve as a comprehensive review of basic Neurology for practicing Psychiatrists as well as physicians in General Medicine and Family Practice. All aspects of the basic and clinical sciences of Neurology will be covered with major emphasis on video-tape presentations of neurological patients. Published text and printed syllabus will be provided. INFORMATION: Division of Continuing Medical Education, University of Miami School of Medicine, P.O. Box 520875, Miami, FL 33152. Tel. (305) 547-6716

Flexibility is our forte: The Brown Schools

Because we maintain great flexibility at all three of our treatment centers, each resident follows an individualized plan of treatment, training, education and care prescribed for that resident alone.

And we believe that residential treatment conducted in this highly individualized manner still is the most effective treatment for many. Our large, experienced staff is skilled in the treatment of children, adolescents and adults with learning disabilities, neurological impairment, mental retardation or emotional disturbance.

Our three treatment centers are geographically separated to provide the appropriate residential milieu, yet close enough that residents benefit from the comprehensive training and expertise of the entire staff. All three are psychiatrically oriented, so that we are prepared to treat emotional disturbance in persons of any intellectual capacity and of any age.

THE BROWN SCHOOLS

An equal opportunity employer

From the Sleep Research Laborator

Dalmane® (flurazepam HC proved the most effective hypnotic over 14 nights...[1]

For those patients who need it, Dalmane (flurazepam HCl) alone provides continued effectiveness[2,3]

Since insomnia is often transient and intermittent, the prolonged administration of a hypnotic is generally not necessary or recommended. But for those patients whose insomnia is a chronic problem, the continued effectiveness of Dalmane is a decided benefit. Even at the end of a 28-night medication period, patients with chronic insomnia were falling asleep faster, spending less time awake during the night, and sleeping substantially longer on Dalmane 30 mg *h.s.* than on baseline placebo nights (average results). This effectiveness was proved[2] and confirmed[3] in two independent sleep research studies using a new 47-night protocol. When similarly evaluated, pentobarbital was ineffective at the end of two weeks.[2]

TOTAL SLEEP TIME (MEAN
(5 patients with insomnia)

*Significantly increased over baseline placebo (p<

14 consecutive nights:
3 in sleep laboratory, 8 at home,
3 in sleep laboratory

...and now, the only one proved effective over 28 nights.[2,3]

In previous studies,[1] chloral hydrate and glutethimide lost most or all effectiveness

In fact, continued effectiveness for both inducing and maintaining sleep over 14 consecutive nights[1] has long been an exclusive benefit of Dalmane. No other available sleep agent, including chloral hydrate or glutethimide,[1] has been able to demonstrate such effectiveness in the sleep research laboratory.

The safety record of Dalmane (flurazepam HCl) is well established

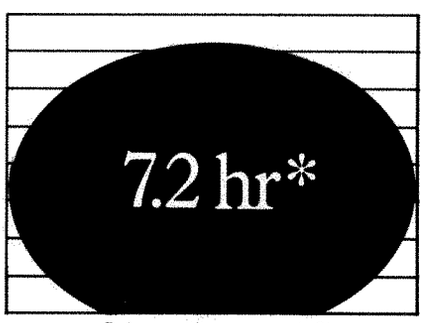
Dalmane is relatively safe and well tolerated. Prolonged administration is not generally necessary, but if used repeatedly, periodic blood counts and liver and kidney function tests should be performed.

Dalmane®
(flurazepam HCl)

relatively safe... no need to increase dosage

ROCHE

28 consecutive nights:
3 in sleep laboratory, 7 at home,
4 in sleep laboratory, 10 at home,
4 in sleep laboratory[3]



Please see following page for a summary of product information.

1,5,7,14,28 nights... as needed, the effectiveness of Dalmane® one *h.s.* (flurazepam HCl) C IV meets the challenge of insomnia

One 30-mg capsule *h.s.*—usual adult dosage (15 mg may suffice in some patients).
One 15-mg capsule *h.s.*—initial dosage for elderly or debilitated patients.

- **Patients fall asleep rapidly, sleep longer on a single *h.s.* dose**
- **Nighttime awakenings and time spent awake are reduced**
- **Effectiveness maintained without dosage increase from night to night**
- **Patients generally awaken refreshed; morning "hangover" is infrequent**

TOTAL SLEEP TIME (OVERALL MEAN)[3]
(5 patients with insomnia)

Dalmane (flurazepam HCl)
nights 1-3, 12-14, 26-28

*Significantly increased over baseline placebo ($p < .05$).

2. Kales A, *et al*: *Clin Pharmacol Ther* *18*:356-363, Sep 1975
3. Dement WC, *et al*: Long-term effectiveness of flurazepam 30 mg *h.s.* on chronic insomniacs. Presented at the 15th annual meeting of the Association for Psychophysiological Study of Sleep, Edinburgh, Scotland, Jun 30-Jul 4, 1975

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).
***Usage in Pregnancy:* Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane (flurazepam HCl), a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit initial dosage to 15 mg to preclude oversedation, dizziness and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

ROCHE

ROCHE LABORATORIES
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

"I'm just a shadow of what I used to be."

That is what depressed individuals may feel is the substance of their being. There is no pleasure, no joy – nothing grows – and in the cold shadow of depression their activities are inhibited, while initiative may be eroded or destroyed. The tragedy is that they can see that others are able to live on the brighter side but they, themselves, cannot reach it on their own.

Your experience in treating depression, and Tofranil-**PM** can help light the way.

Tofranil-**PM**®
imipramine **pamoate**

Geigy

Unsurpassed effectiveness among tricyclics in relieving symptoms of anxious depression.

Before prescribing Tofranil-PM, please review a summary of the prescribing information on the back of this page.

Tofranil-PM®
imipramine **pamoate**

Geigy

As anxiety, agitation, sleep disturbances, and other depressive symptoms are relieved, mood and motivation may be markedly improved.

Patients are usually alert and capable of functioning at more normal levels of behavior.

Tofranil-PM encourages patient compliance because one capsule lasts from bedtime to bedtime.

Good results are usually seen at the starting dose of one 75-mg capsule h.s.

For many patients, dosage can be safely increased to 150 mg daily.

As with all tricyclics, sedation may occur. Please caution patients against driving or operating dangerous machinery.

Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Tofranil-PM®
brand of imipramine pamoate

Indications: For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications: The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

—patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
—patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
—hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
—patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
—patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as operating an automobile or machinery, the patient should be cautioned accordingly.

Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Adverse Reactions: Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

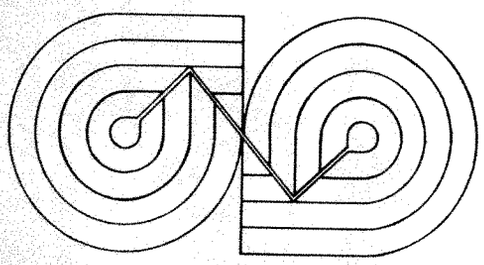
Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: In adult outpatients, therapy should be initiated on a once-a-day basis with 75 mg./day. This may be increased to 150 mg./day which is the dose level which usually obtains optimum response. If necessary, dosage may be increased to 200 mg./day. Dosage should be modified as necessary by clinical response and any evidence of intolerance. Daily dosage may be given at bedtime, or in some patients in divided daily doses.

Hospitalized patients should be started on a once-a-day basis with 100-150 mg./day and may be increased to 200 mg./day. Dosage should be increased to 250-300 mg./day if there is no response after two weeks.

Following remission, maintenance medication may be required for a longer period of time at the lowest dose that will maintain remission. The usual adult maintenance dosage is 75-150 mg./day on a once-a-day basis, preferably at bedtime.



In adolescent and geriatric patients, capsules of Tofranil-PM, brand of imipramine pamoate, may be used when total daily dosage is established at 75 mg. or higher. It is generally unnecessary to exceed 100 mg./day in these patients. This dosage may be given once a day at bedtime or, if needed, in divided daily doses.

How Supplied: Tofranil-PM, brand of imipramine pamoate: Capsules of 75, 100, 125 and 150 mg. (Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg. of imipramine hydrochloride.)

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

"Now Andy's classmates laug

vith him, not at him"

Today, direct coaching in appropriate social interaction, role playing, and encounter techniques are being used to help hyperactive children overcome disruptive social behavior patterns that often cause them to become objects of ridicule to their peers.

Ritalin, when indicated, can also play a useful role in this respect, as improving social interaction in the MBD child often involves reducing hyperactivity. Indeed, as one investigator[1] has reported, with Ritalin therapy, the MBD child can be less aggressive, less impulsive, and better able to interact with his peers. Other studies also report improved social behavior of MBD children on Ritalin.[2,3]

A drug of choice when treatment of MBD is indicated,[4,5] controlled studies and clinical experience have demonstrated the ability of Ritalin to effectively reduce hyperactivity,[1,2] distractibility,[1,3] and disorganized behavior[1,3,6-8] in the MBD child.

And these symptomatic improvements achieved with Ritalin often result in the child being more responsive to the nonpharmacological measures of the MBD management team.[8]

Although side effects – insomnia and appetite loss – are occasionally seen with Ritalin, they are less frequent or severe than with dextroamphetamine.[4,10]

Therapy with Ritalin should be undertaken only after a medical diagnosis of MBD has been made. Dosage should be periodically interrupted. Often these interruptions reveal some "stabilization" in the child's behavior even without medication. In some MBD children they permit a reduction in dosage and eventual discontinuance of drug therapy.

Ritalin...Only when medication is indicated

Ritalin® (methylphenidate) C II

(methylphenidate hydrochloride)
TABLETS

INDICATION

Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)

Special Diagnostic Considerations

Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation, since Ritalin may aggravate these symptoms. Also contraindicated in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain and/or height) has been reported with long-term use of stimulants in children. Therefore, children requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin or for the prevention of normal fatigue states.

Ritalin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children with Minimal Brain Dysfunction (6 years and over).

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500, and 1000.

Consult complete product literature before prescribing.

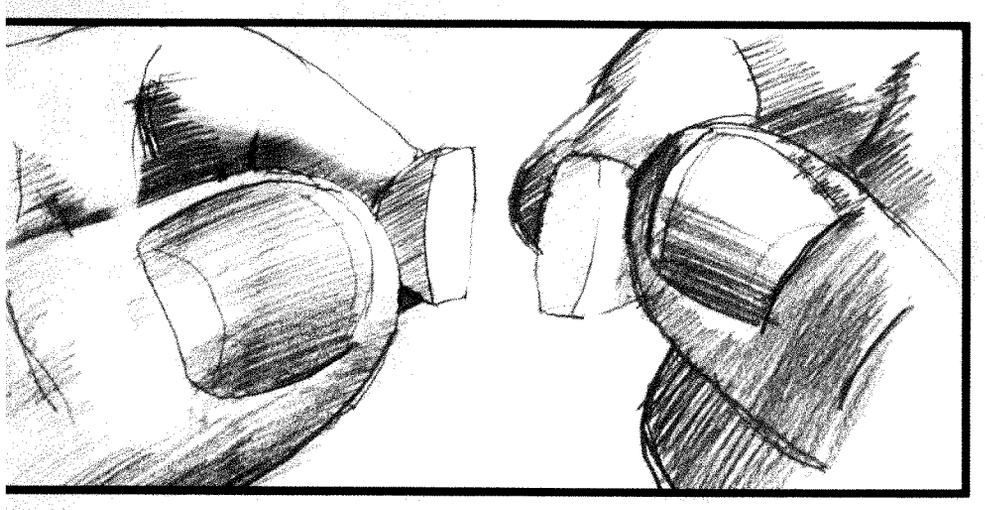
Why Endep® make
with amitriptyline HC

Scored tablets h.s. enhance compliance and tolerability

Once you select the appropriate maintenance dose, you can prescribe a single tablet of Endep h.s. secure in the knowledge that you can adjust the dose by a half tablet without requiring the patient to obtain a new Rx. The simplicity of this h.s. schedule not only encourages compliance, but lessens the likelihood of anticholinergic and sedative side effects during daytime.

Scored tablets h.s. reduce confusion



Bedtime dosage means that the patient has only one dose of Endep to remember, thus minimizing possible confusion with other medications taken concomitantly. The built-in flexibility of the scored tablet permits half-strength dosage adjustments without confusing the patient with a new color or size of medication.

ROCHE

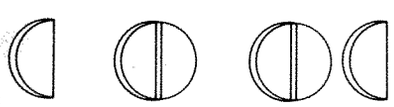
ng-term maintenance
ore practical:

Scored tablets b.s. promote economy

The economy of Endep (amitriptyline HCl) is particularly evident ing long-term maintenance therapy, when your patient is purchasing refills of single strength you have prescribed. The b.s. schedule enables you to prescribe ngle strength in place of a more expensive multiple-dose prescription. The scored let permits you to adjust the regimen without putting the patient through the ense of a new prescription fee, without wasting tablets and without necessitating purchase of more costly multiple-dose refills.

Endep®
amitriptyline HCl/Roche

The half-strength advantage



Before prescribing, please see following page for a summary of product information.

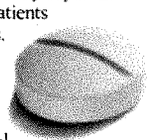
Practicality is a fundamental fact about Endep®

amitriptyline HCl/Roche

Every tablet of Endep (amitriptyline HCl) is scored for precise, convenient adjustment of dosage.

Half-tablet adjustment of dosage does not require a new Rx.

Single daily *h.s.* dosage promotes compliance and economy.



Compliance with practical regimen promotes optimal response.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depression) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

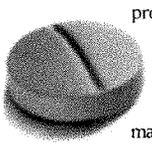
Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle-closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

100 mg

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels.

10 mg



50 mg

25 mg

75 mg

150 mg

Other: Dizziness weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction

Dosage: Initiate at low levels, increase gradually, watching for sign of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier.

Initial Adult Dosage: Outpatients—25 mg *t.i.d.*; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate—50 to 100 mg *h.s.*, gradually increasing *h.s.* dose up to 150 mg/day. Hospitalized Patients—Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day.

Adolescent and Elderly Patients: In general, 10 mg *t.i.d.* with 20 mg *h.s.* may be satisfactory for those who do not tolerate higher doses.

Maintenance Dosage: With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg *b.i.d.* to *q.i.d.*, or 10 mg *q.i.d.* Continue maintenance therapy 3 months or longer to avoid relapse.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg, 75-mg, 100-mg and 150-mg scored tablets—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg, 100 mg and 150 mg), available singly and in trays of 10.

MANUAL OF PSYCHIATRIC PEER REVIEW

by the Peer Review Committee of the American Psychiatric Association, Donald G. Langsley, M.D., Chairperson in cooperation with the Joint Task Force on Diagnostic Criteria for Analyzability of the American Psychoanalytic Association, William Offenkrantz, M.D., Chairperson, and the Peer Review Committee of the American Academy of Child Psychiatry. Larry B. Silver, M.D., Chairperson.

"This Manual provides a set of guidelines for district branches of APA and their peer review committees which should be adapted and modified in terms of local criteria, standards, and practices. The guidelines are not intended to be hard and fast rules. They are screening criteria, and not regulations to control practice. They are so designed that they can be utilized by non-physicians to identify those cases that can profitably be reviewed by psychiatrists serving on peer review committees. This document should be viewed as transitional, subject to revision as experience is gained, and continually updated in response to advances in psychiatric knowledge and changes in patterns of practice. . . . The application of these standards, and refinement through experience must rest with the peer review committees of district branches. . . . It should help them to move ahead in the development of a peer review for American psychiatry."

Robert W. Gibson, M.D.
President

Part I titled PSYCHIATRIC PEER REVIEW contains sections on Basic Relationships and Responsibilities, Appointment of Peer Review Committees, Funding, Operations and Procedures, Medical Care Evaluation Studies, Appeals Processes, Special Problems, Confidentiality, Educational Aspects, Medical Ethics, Advocacy, Interdisciplinary Aspects, with Appendices on Model Screening Format for Inpatient Treatment for Alcoholism, Model Screening Format for Outpatient Treatment, Sample Form for Requesting Extension of Office Treatment, Claims Review Guidelines Suggestions, APA Position Papers on Peer Review, Bibliography.

Part II titled PSYCHOANALYTIC PEER REVIEW has sections on Steps in Peer Review for Psychoanalysis, Guidelines for Model Criteria Sets, Pilot Application of Guidelines for Model Criteria Sets, Sample Peer Review Form, Sample data from Pilot Applications of Guidelines, and Glossary of Terms Used.

Part III titled PEER REVIEW AND CHILD PSYCHIATRY contains sections of Special Considerations, Legal Rights of Children, Issue of Confidentiality, Conclusions, References, and Appendices on Model Screen Criteria Format for Intermediate Care, for Acute Care in a Short Stay Facilities, and for Partial Hospitalization, Outpatient Diagnostic Evaluation Procedures, and Outpatient Treatment for Children and Adolescents.

in short-term therapy of moderate to marked depression with variable degrees of anxiety in patients with depressive neurosis

MELLARIL®
(THIORIDAZINE)

TABLETS: 10 mg, 15 mg, 25 mg, and 50 mg thioridazine HCl, USP

RESULTS OFTEN SEEN IN A WEEK

©1977 Sandoz, Inc.

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient. In adults with depressive neurosis the usual starting dosage is 25 mg t.i.d. and the dosage ranges from 10 mg b.i.d. to q.i.d. in milder cases to 50 mg t.i.d. or q.i.d. for more severely disturbed patients; the total daily dose ranges from 20 mg to a maximum of 200 mg.

THE AMERICAN JOURNAL OF PSYCHIATRY

The Brain as a Dream State Generator: An Activation-Synthesis Hypothesis of the Dream Process

BY J. ALLAN HOBSON, M.D., AND ROBERT W. MCCARLEY, M.D.

Recent research in the neurobiology of dreaming sleep provides new evidence for possible structural and functional substrates of formal aspects of the dream process. The data suggest that dreaming sleep is physiologically determined and shaped by a brain stem neuronal mechanism that can be modeled physiologically and mathematically. Formal features of the generator processes with strong implications for dream theory include periodicity and automaticity of forebrain activation, suggesting a preprogrammed neural basis for dream mentation in sleep; intense and sporadic activation of brain stem sensorimotor circuits including reticular, oculomotor, and vestibular neurons, possibly determining spatiotemporal aspects of dream imagery; and shifts in transmitter ratios, possibly accounting for dream amnesia. The authors suggest that the automatically activated forebrain synthesizes the dream by comparing information generated in specific brain stem circuits with information stored in memory.

SINCE THE TURN of the century, dream theory has been dominated by the psychoanalytic hypothesis that dreaming is a reactive process designed to protect consciousness and sleep from the disruptive effect of unconscious wishes that are released in sleep (1). Thus dreaming has been viewed as a psychodynamically determined state, and the distinctive formal features of dream content have been interpreted as manifestations of a defensive transformation of the unconscious wishes found unacceptable to consciousness by a hypothetical censor. A critical tenet of this wish fulfillment-disguise theory is that the transformation of the unconscious wish by the censor disguises or degrades the ideational information in forming the dream imagery. We were surprised to discover the origins of the major tenets of psychoanalytic dream theory in the neurophysiology of 1890 and have specified the transformations made by Freud in an earlier, related article (2). In detailing the neurophysiological origins of psychoanalytic dream theory, the concept of mind-body isomorphism, denoting similarity of form between psychological and physiological events, was seen as an explicit premise of Freud's thought.

Sharing Freud's conviction that mind-body isomorphism is a valid approach, we will now review modern neurophysiological evidence that we believe permits and necessitates important revisions in psychoanalytic dream theory. The activation-synthesis hypothesis that we will begin to develop in this paper asserts that many formal aspects of the dream experience may be the obligatory and relatively undistorted psychological concomitant of the regularly recurring and physiologically determined brain state called "dreaming sleep." It ascribes particular formal features of the dream experience to the particular organizational features of the brain during that state of sleep. More specifically, the theory details the mechanisms by which the brain becomes periodically activated during sleep and specifies the means by which both sensory input and motor output are simultaneously blocked, so as to account for the maintenance of sleep in the face of strong central activation of the brain. The occurrence and character of dreaming are seen as both determined and shaped by these physiological processes.

Based on the text of the Sandoz Lecture presented by Dr. Hobson at the University of Edinburgh, April 23, 1975.

Dr. Hobson is Associate Professor of Psychiatry and Dr. McCarley is Assistant Professor of Psychiatry, Harvard Medical School, Boston, Mass. Dr. Hobson is also Director and Dr. McCarley is Co-Director, Laboratory of Neurophysiology, Massachusetts Mental Health Center, 74 Fenwood Rd., Boston, Mass. 02115.

The research described herein was supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-13923 from the National Institute of Mental Health and by the Milton Fund of Harvard University.

The authors wish to express their appreciation to Drs. John Nemiah and John Nelson for their helpful comments on the manuscript.

The most important tenet of the activation-synthesis hypothesis is that during dreaming the activated brain generates its own information by a pontine brain stem neuronal mechanism, which will be described in detail. We hypothesize that this internally generated sensorimotor information, which is partially random and partially specific, is then compared with stored sensorimotor data in the synthesis of dream content. The functional significance of the brain activation and the synthesis of endogenous information in dreaming sleep is not known, but we suggest that state-dependent learning is at least as likely a result of dreaming as is tension reduction or sleep maintenance.

While we believe that the two processes emphasized in this paper—activation and synthesis—are major and important advances in dream theory, we wish to state explicitly and comment on some of the things that our theory does not attempt to do. The activation-synthesis hypothesis does not exclude possible defensive distortions of the value-free sensorimotor dream stimuli, but it does deny the primacy of any such process in attempting to explain *formal* aspects of dream content or the fundamental impetus to dreaming itself. The idea that dreams reveal wishes is also beyond the direct reach of our new theory, but some specific alternatives to this interpretation of several classic dream situations can be advanced.

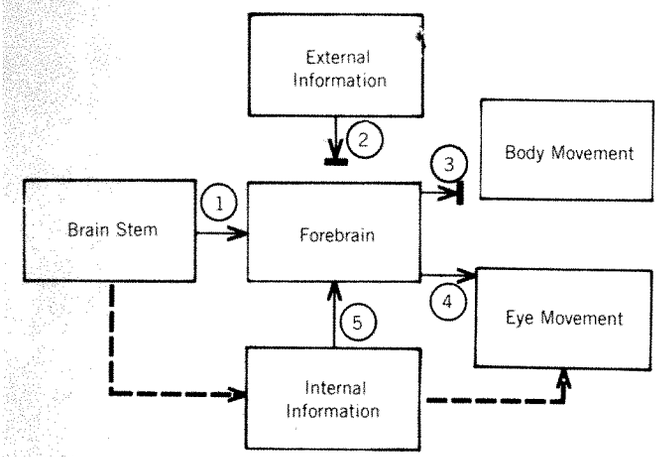
The new theory cannot yet account for the emotional aspects of the dream experience, but we assume that they are produced by the activation of brain regions subserving affect in parallel with the activation of the better known sensorimotor pathways. Finally, the new theory does not deny meaning to dreams, but it does suggest 1) a more direct route to their acquisition than anamnesis via free association, since dream origins are in basic physiological processes and not in disguised wishes, 2) a less complex approach to their interpretation than conversion from manifest to latent content, since unusual aspects of dreams are not seen as disguises but as results of the way the brain and mind function during sleep, and 3) a broader view of their use in therapy than that provided by the transference frame of reference, since dreams are not to be interpreted as the product of disguised unconscious (transference) wishes. Dreams offer a royal road to the mind and brain in a behavioral state, with different operating rules and principles than during waking and with the possibility of clinically useful insights from the product of these differences. These points are discussed in the last section of this paper and elsewhere (3).

WHAT IS A DREAM?

A dream may be defined as a mental experience, occurring in sleep, which is characterized by hallucinoid imagery, predominantly visual and often vivid; by bizarre elements due to such spatiotemporal distortions as condensation, discontinuity, and acceleration; and by a delusional acceptance of these phenomena as "real" at the time that they occur. Strong emotion may or may not be associated with these distinctive formal properties of the dream, and subsequent recall of these mental events is almost invariably poor unless an immediate arousal from sleep occurs.

TABLE 1
Electrographic Criteria for Behavioral State Determination

State	Electromyogram	EEG	Electrooculogram
Waking	+	Low voltage, fast	+
Sleep			
Synchronized	+	High voltage, slow	—
Desynchronized	—	Low voltage, fast	+



That this technical jargon describes a universal human experience seems certain, since the five key points in this definition are easily elicited from both naïve and sophisticated individuals when they are asked to characterize their dreams. We leave aside the question of whether other less vivid and nonperceptual forms of mental activity during sleep should also be called "dreams" and confine ourselves here to the psychophysiology of the hallucinoid type of dream. In doing so, we not only simplify the immediate task at hand but may also gain insight into the mechanisms underlying the most florid symptoms of psychopathology. We mean, of course, the hallucinations and delusions of the psychotic experience, which have so often invited comparison with the dream as we have defined it here.

WHAT IS THE STATE OF THE BRAIN DURING DREAMING SLEEP?

The physiological substrate of the dream experience is the CNS in one of its three principal operating states: waking (W), synchronized sleep (S), and desynchronized sleep (D). These states can be reliably and objectively differentiated by recording the EEG, the electromyogram (EMG), and the electrooculogram (see table 1). Hallucinoid dreaming in man occurs predominantly during the periodically recurrent phase of sleep characterized by EEG desynchronization, EMG suppression, and REMs (4). We call this kind of sleep "D" (meaning desynchronized, but also conveniently denoting dreaming).

In the systems analysis terms used in figure 1, this D brain state is characterized by the following "sensorimotor" properties: activation of the brain; relative exclusion of external input; generation of some internal input, which the activated forebrain then processes as information; and blocking of motor output, except for the oculomotor pathway. In this model the substrate of emotion is considered to be a part of the fore-

4. Oculomotor activation
5. Provision of forebrain with internally generated information

brain; it will not be further distinguished here because we have no specific physiological evidence as to how this part of the system might work in any brain state. Memory is not shown but is considered to be a differentiated function of the brain that operates during the D state, such that output from long-term storage is facilitated but input to long-term storage is blocked. A highly specific hypothesis about dream amnesia has previously been derived (5) from the same evidence that we will now review in our attempt to account for the general sensorimotor aspects of the dream process.

ELECTROPHYSIOLOGY OF THE BRAIN DURING THE DREAM STATE

The three major electrographic features of the D state are of obvious relevance to our attempt to answer the following three questions about the organization of the brain in the dream state.

How is the forebrain activated in the D state? Since EEG desynchronization also characterizes waking, similar mechanisms of "activation" may be involved in both instances. Physiological evidence suggests that this is so: the reticular formation of the anterior brain stem is at least as active in D sleep as it is in the waking state (see figure 2).

How is motor output blocked in the D state? Physiological evidence clearly shows that the profound EMG suppression of D sleep is a consequence of the direct inhibition of spinal cord motoneurons (6). As a consequence, any organized motor patterns that might be generated during the intense brain activation of D sleep cannot be expressed.

That organized movement patterns are in fact generated, but not expressed, in normal D sleep is dramatically demonstrated by cats with lesions of the anterodorsal pontine brain stem (7). The animals show all of the major manifestations of D sleep except the atonia; instead of the fine twitches of the digits and the limb jerks that are normally present in D, these cats display complex motor behaviors including repetitive paw movements and well-coordinated attack and defense sequences that have no apparent relationship to the environment.

How is sensory imagery generated in the D state? In waking, a corollary discharge of the oculomotor system has been shown to suppress visual transmission during saccadic eye movements, possibly contributing to the stability of the visual field during that state (8). The same mechanisms might underlie the hallucinoid dream imagery by inhibiting and exciting neurons of the lateral geniculate body (9) and the visual cortex (10) during D sleep, when retinal input is reduced and unformed.

The possibility that oculomotor impulses trigger visual imagery is particularly intriguing in view of the demonstrated quantitative correlation between eye

movement intensity and dream intensity (11). More specific correlations have also been reported to relate eye movement direction to orientation of the hallucinated gaze in dreams (12). This finding has been interpreted as indicative of "scanning" the visual field—implying cortical control of the eye movements in dreaming sleep. An alternative, although not exclusive, hypothesis is that the oculomotor activity is generated at the brain stem level and that the cortex is then provided with feed-forward information about the eye movements. According to this view, we are not so much scanning dream imagery with our D sleep eye movements as we are synthesizing the visual imagery appropriate to them. We will return to the implications of this intriguing possibility in discussing the generation of eye movements in dreaming sleep, but we wish to stress here the general significance of this clue to the identity of an "internal information generator" operating at the brain stem level in the dreaming sleep state.

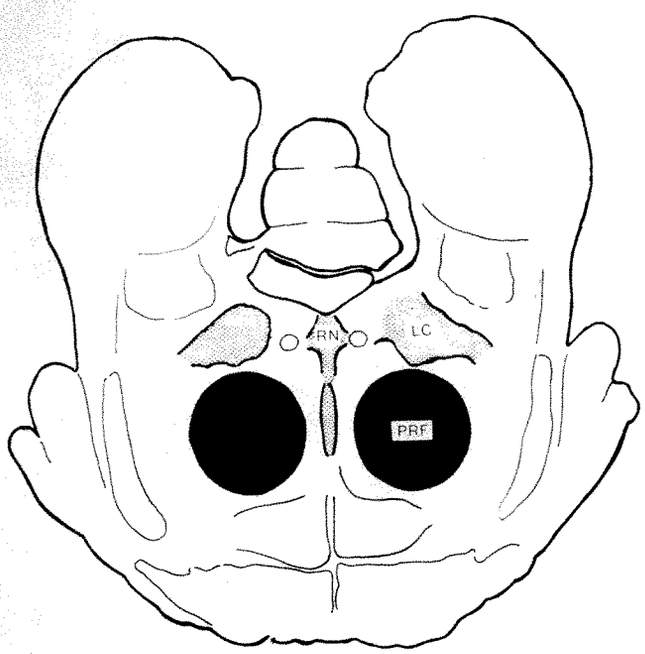
The eye-movement-related inhibition of sensory relays (13), as well as the possible occlusion of exogenous inputs by internally generated excitation, may also contribute to the maintenance of sleep in the face of strong central activation of the brain. In this sense the dream process is seen as having a sleep maintenance mechanism built into its physiological substrate rather than a sleep guardian function operating at the psychological level.

A firm general conclusion can be reached at this point: the desynchronized phase of sleep is the physiological substrate of hallucinoid dreaming, as defined. This conclusion is of profound significance to psychophysiology, since we can now reliably and objectively characterize and measure many aspects of the brain when it is in the dream state. For example, one feature that emerges from the psychophysiological study of dreaming and one that was not at all evident from introspective, psychoanalytically oriented research, is that the brain enters the dream state at regular intervals during sleep and stays in that state for appreciable and predictable lengths of time. One clear implication of this finding is that dreaming is an automatically preprogrammed brain event and not a response to exogenous (day residue) or endogenous (visceral) stimuli. A second implication is that the dream state generator mechanism is periodic, that is, the dream state generator is a neurobiological clock (14). Since the length of the sleep cycle and, by inference, the frequency of dreaming, is a function of body size within and across mammalian species (15), the system controlling the length of the period must have a structural substrate. Thus we must account for size-related periodicity with our model of the dream state generator.

AN ANIMAL MODEL OF THE BRAIN DURING THE DREAM STATE

We said that the length of the sleep cycle varies "across species." Does that mean that nonhuman animals dream? Unfortunately we cannot know, but we are willing to assert that if they do so, it is when their brains are in the D sleep state. Because we have no direct evidence of any significant difference between the brain state of man and the brain state of other mammals in D sleep, we therefore feel justified in asserting that the brain state of our experimental animal, the cat, constitutes a reasonable subject for our study of the brain as a dream process generator, whether or not cats dream. This assertion seems justified since we are restricting our attention here to formal aspects of the dream experience; our experimental model need not dream or even possess "consciousness" to be useful as a source of physiological information. If we accept this argument and use the definition of dreaming offered above, then the presence of D sleep in cats (16) offers nothing less than an animal model in which to study the neurophysiological basis of a hallucinoid mental process in man. Such a model is as important in experimental psychiatry as it is rare. Let us now turn to the biological data upon which our sketches of the brain as a dream state generator are based.

LOCALIZATION OF THE POWER SUPPLY OR TRIGGER ZONE OF THE DREAM STATE GENERATOR



Lesion, stimulation, and recording studies pioneered by Jouvet (17) have strongly implicated the pontine brain stem as critical to the generation of the desynchronized sleep phase (see figure 3 for a summary of the neuroanatomy of this region). Important findings supporting this hypothesis include the following.

Large lesions of the pontine reticular formation prevent the occurrence of desynchronized sleep for several weeks in cats (17). This suggests that the pontine reticular formation may be the site of an executive or triggering mechanism for desynchronized sleep. Prepontine transections and forebrain ablation have no effect upon periodicity or duration of the skeletal, muscular, and oculomotor manifestations of D sleep (17). The data indicate that the trigger, the power supply, and the clock are pontine.

The pontine brain stem is thus implicated as the site of both the trigger and the clock. The periodicity of the D sleep clock in poikilothermic pontine cats lengthens as temperature declines, indicating orthodox metabolic mediation of the cycle, in contrast to the temperature independence of circadian rhythms. If we assume that the physiological substrate of consciousness is in the forebrain, these facts completely eliminate any possible contribution of ideas (or their neural substrate) to the primary driving force of the dream process.

Small lesions of the dorsal pontine brain stem, in the region of the locus coeruleus (LC), may eliminate the atonia but no other aspects of desynchronized sleep (7). This suggests that inhibition of muscle tone

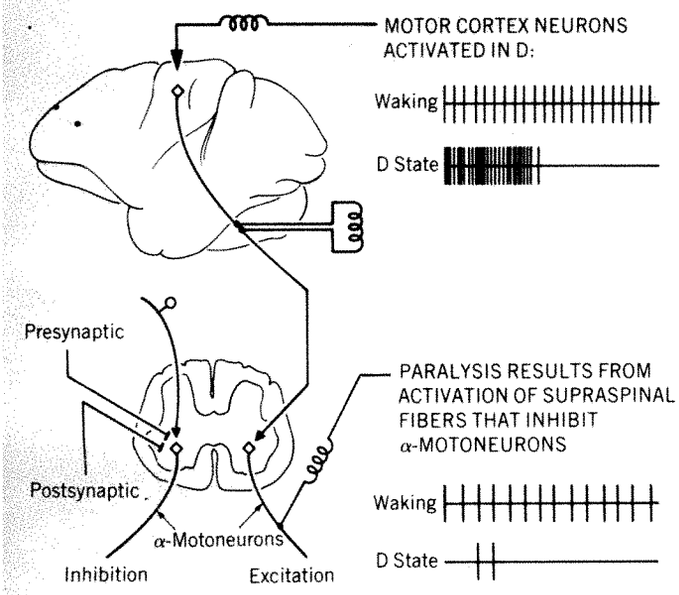
FIGURE 3
The Anatomy of the Pontine Brain Stem*

*On this frontal section of the cat brain stem, the cells that are selectively activated are in the paramedian reticular formation (PRF) (giganto cellular tegmental field), while the cells that are selectively inactivated lie more dorsally (in the region of the locus coeruleus [LC]) and medially (in the region of the raphe nuclei [RN]). Compare this with figure 5, which summarizes the neurophysiology and shows the anatomy in a sagittal section.

is somehow dependent upon the integrity of the LC. The elaborate motor behavior that characterizes the D sleep of cats with LC lesions has been described as "pseudo-hallucinatory" (7). Whether or not one accepts the sensory implications of that designation, the importance of motor inhibition in quelling the effects of central excitation during the dream state is clear.

This finding has an important bearing on mechanisms of dream paralysis and suggests that in the classic chase dream, the dreamer who has trouble fleeing from a pursuer is as much accurately reading the activated state of his motor pattern generator and the paralyzed state of his spinal neurons as he is "wishing" to be caught. This dream experience is so universal and the feeling of constrained motor action so impressive as to make its physiological basis in the descending inhibition of motoneurons seem to us inescapable. Conversely, this reasonable and adequate explanation of the paradox of the chase dream makes its interpretation as wish fulfillment less compelling. Other implications of the D sleep activation of various motor system pattern generators for movements and dream plots have been discussed elsewhere (3).

The vestibular system, as classically established, integrates head position and movement with eye position and posture. Pompeiano and Morrison (18) showed that lesions of the vestibular nuclei interfered with the bursts of REM but not with the isolated eye movements of D. This finding suggested that the vestibular system contributed to the elaboration and rhythmicity of the eye movements but that the eye movement generator was extravestibular. Magherini and associates (19) found that systemic injections of the anticholinesterase agent physostigmine produced rhythmic eye movements in decerebrate cats, suggesting that the eye movement generator may be cholinergic. Thus the central, automatic activation during sleep of the vestibular system may provide a substrate for endogenously generated, specific information about body position and movement. Flying dreams may thus be a logical, direct, and unsymbolic way of synthesizing information generated endogenously by the vestibular system in D sleep. In view of this reasonable and direct explanation, it seems gratuitous to "interpret" the sensual flying dream as sexual.



In accord with the isomorphism principle, the degree of neuronal activation in brain systems should parallel the frequency and intensity of dreams to these systems (3), and the predominance of visual sensorimotor activity in both brain and mind supports this notion. Symbol formation and the often bizarre juxtaposition of sensations in the dream may be a reflection of the heightened degree of simultaneous activation of multiple sensory channels in dreaming as compared with waking (3).

Long-term electrical stimulation of the pontine brain stem results in the earlier appearance of sleep episodes and in increases in the absolute amounts of desynchronized sleep, but it does not affect the periodicity of its occurrence (20). By implication, the delivery of electrical energy accomplishes what most psychological and behavioral treatments fail to achieve: an increase in the duration of dreaming sleep. Testing the assumption that the generator neurons are cholinoceptive, our laboratory team has recently established that injection of the cholinergic agent carbachol into the pontine reticular formation produces prolonged enhancement of D-like sleep behavior (21). In man the parenteral injection of the anticholinesterase agent physostigmine potentiates D sleep, and the pharmacologically induced episodes are associated with hallucinoid dreaming (22). The time of occurrence and duration of dreams may thus be chemically determined.

In summary, these results support the hypothesis that the pontine brain stem is the generator zone for the D sleep state. The trigger mechanism for the whole system, including the eye movement generator, may be cholinoceptive and the executive zones are probably in the reticular formation. The LC is involved, possibly in a permissive or reciprocal way, and is especially important in mediating spinal reflex inhibition. Together, these two regions may constitute the clock. We will have more to say about the hypothesis of reciprocal interaction between them later in this paper.

Although the brain stem mechanisms mediating atonia remain obscure, it is clear from the work of Pompeiano (6) that both monosynaptic and polysynaptic spinal reflexes are tonically inhibited during D sleep (see figure 4). In addition, during the bursts of REM,

FIGURE 4
Mechanisms of Sleep Paralysis*

*The upper part of the figure illustrates the intense activation in D sleep of antidromically identified pyramidal tract neurons of the motor cortex. Note the relatively regular discharge in waking (W) and the clustering of discharges in D sleep in these models of 3-second epochs of microelectrode recordings (vertical lines indicate discharges). The lower portion of the figure shows the inhibitory events of D at the spinal cord level that largely prevent alpha motoneuron discharge and consequent muscle excitation, despite the activation of excitatory (arrow) pyramidal tract fibers. Both presynaptic and postsynaptic inhibition (bars) are present in D (sketched on the left side of the cord section). Absence of this inhibition in W allows alpha motoneuron discharge in response to excitation from pyramidal tract fibers (17).

there is a descending presynaptic inhibition of the most rapidly conducting (group 1*a*) spinal afferent endings. Both presynaptic and postsynaptic inhibition appear to be of brain stem origin. Phasic presynaptic inhibition has also been shown to occur in sensory relays elsewhere in the brain during D sleep (6). Thus motor output is tonically damped throughout D and sensory input is phasically damped in concert with the REM bursts. In other words, we are not only paralyzed during our dreams, but the degree to which we are paralyzed fluctuates in concert with the intensity of the internally generated information and the degree to which we suppress exogenous input.

On the basis of this evidence, the systems terminology used earlier (see figure 1) can be tentatively translated into the anatomical and physiological terms of figure 2; and the activation-synthesis hypothesis of dreaming can be stated as follows: during D sleep, a cholinergic mechanism in the reticular formation of the pontine brain stem is periodically activated. The consequences of this activation are as follows:

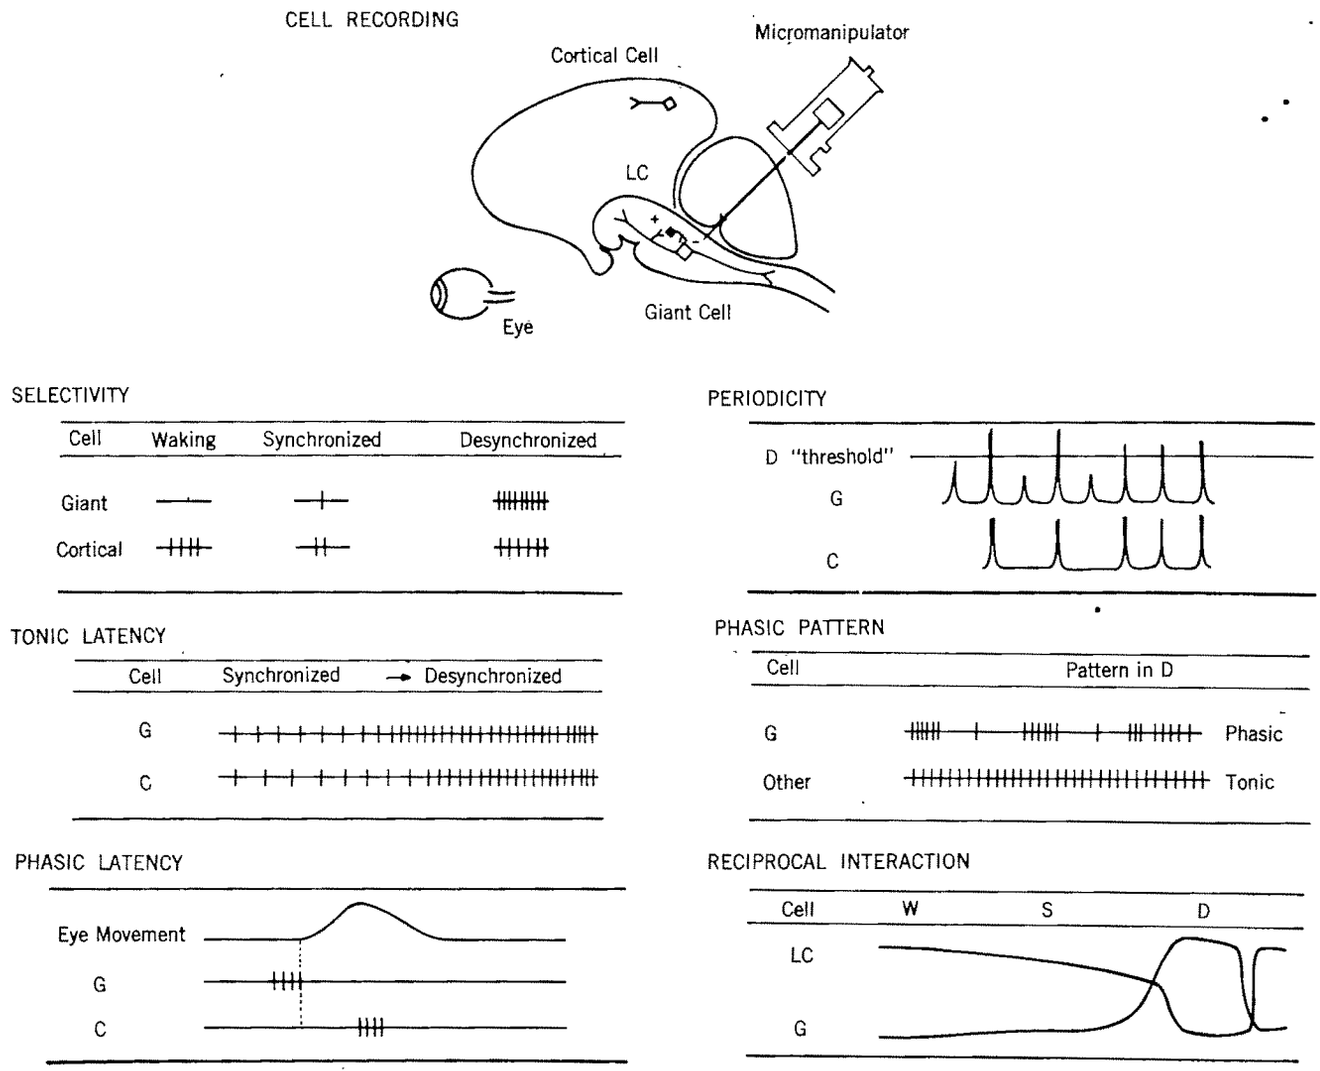
1. The forebrain is tonically activated, probably via the midbrain reticular formation that is also responsible for its activation during waking. Thus the forebrain is made ready to process information.

2. The spinal reflexes are tonically inhibited, possibly via the bulbar reticular formation and LC; thus motor outflow is blocked despite high levels of activity in the brain, including the motor cortex.

3. The oculomotor and vestibular systems are phasically activated by the pontine reticular formation so as to produce eye movements. This circuitry, in its entirety, is an internal information source or generator that provides the forebrain with spatially specific but temporally disorganized information about eye velocity, relative position, and direction of movement. Information may similarly be derived from the brain stem generators of patterned motor activity.

4. At the same time that internal information feedback is being generated by the activation of various motor systems, exteroceptive input to sensory systems is phasically blocked. This may intensify the relative impact of the endogenous inputs to the brain, accounting for the intensity of dream imagery and preventing sleep disruption by the externally generated excitation.

This working sketch of the dream state generator, based on the classical localizing methods of experimental neurology, is intriguing but unsatisfying in that it fails to specify the mechanisms by which the pontine generator is turned on, kept active for a time, and then shut off. Further, it does not say anything about the mechanism of periodicity. To provide details about the anatomy and physiology of the periodic trigger mechanisms of the generator process, we will now turn our attention to the neuronal level of analysis. In doing so, we also come full circle in our reaffirmation of isomorphism since it was the neuron that Freud recognized as the physical unit of the nervous system on which he based his dream theory (2).



HISTOLOGICAL FEATURES OF RELEVANCE TO THE PERIODIC TRIGGERING OF THE DREAMING SLEEP STATE GENERATOR

Several structural details of the pontine brain stem are notable as possible elements of a D sleep control device with rhythmic properties (see figure 3 for an illustration of the anatomy discussed).

In his discussion of the histology of the pontine brain stem, Cajal (23) emphasized three points:

1. The paramedian reticular giant cells, with their rostral and caudal axonal projections, are admirably suited to serve as output elements of the generator; when excited they could influence many other cells. The work of Brodal (24) and the Scheibels (25) shows that the spinal cord and thalamus receive projections from these elements. Although they are relatively few in number, conservative estimates of their postsynaptic domain indicate that each directly projects to nine million (9×10^6) postsynaptic neurons. Thus the 3,000 pontine reticular giant cells in the cat might make many billions of synapses (2.9×10^{10}). Since the giant cells also project to other brain stem nuclei and have recurrent axons to themselves, mutual interaction with raphe-type elements (see below) and self-reexcitation

FIGURE 5
Cellular Neurophysiology of Dream State Generation*

*The cell recordings are made from hydraulically driven microelectrodes that can be stereotaxically directed at neurons in the cat brain during natural sleep. Two classes of brain stem neurons are represented by the reticular giant cell (G in the physiological models) and the LC cell; the synaptic interactions suggested are detailed in figure 8. A cortical cell is also shown.
The results of the cell recording experiments are shown in six models representing the criteria used to quantify discharge properties: selectivity—giant cells concentrate their discharge in D to a greater extent than cerebral cortical or other brain stem neurons; tonic latency—giant cells show rate increases that precede those of cortical neurons during the S to D transition; phasic latency—giant cells fire before the REMs of D, while cortical neurons fire after them; periodicity—peaks in the giant cell activation curves are periodic and the higher peaks are associated with D sleep episodes and peaks of cortical activity; phasic pattern—giant cells show a higher degree of clustered firing in D than do other neurons; and reciprocal interaction—the rate curves of giant cells and LC cells are reciprocal over the sleep cycle.

are both possible. These two features could be used to create excitability variability, with powerful consequences for the whole nervous system.

2. The raphe neurons of the midline are ideally situated and connected to regulate excitability of paramedian elements, and they also have extensive projections to other brain regions. The discovery that these cells concentrate the biogenic amine serotonin (26) gives this regulatory hypothesis an attractive corollary: these cells might regulate excitability of their postsynaptic neurons via specific transmitter substances. Another brain stem cell group, in the locus coeruleus, has been shown to concentrate the amine norepinephrine (26). There are thus at least two neuronal candidates for a level setting role, and both are probably inhibitory. Since the giant cells are excitatory (and probably cholinergic; see below), a substrate for reciprocal interaction is established.

3. Cajal (23) suggested that input to the central reticular core might be via small stellate cells in the lateral zone. This input channel, which we now know to be more diffuse than was originally suspected, could be used to abort or damp the core oscillator at critical ambient stimulus levels. This is an important feature,

since adaptation depends on the capacity to interrupt the cycle and not to incorporate all exogenous stimuli into the dream plot.

CELLULAR ACTIVITY IN THE PONTINE BRAIN STEM DURING THE SLEEP CYCLE

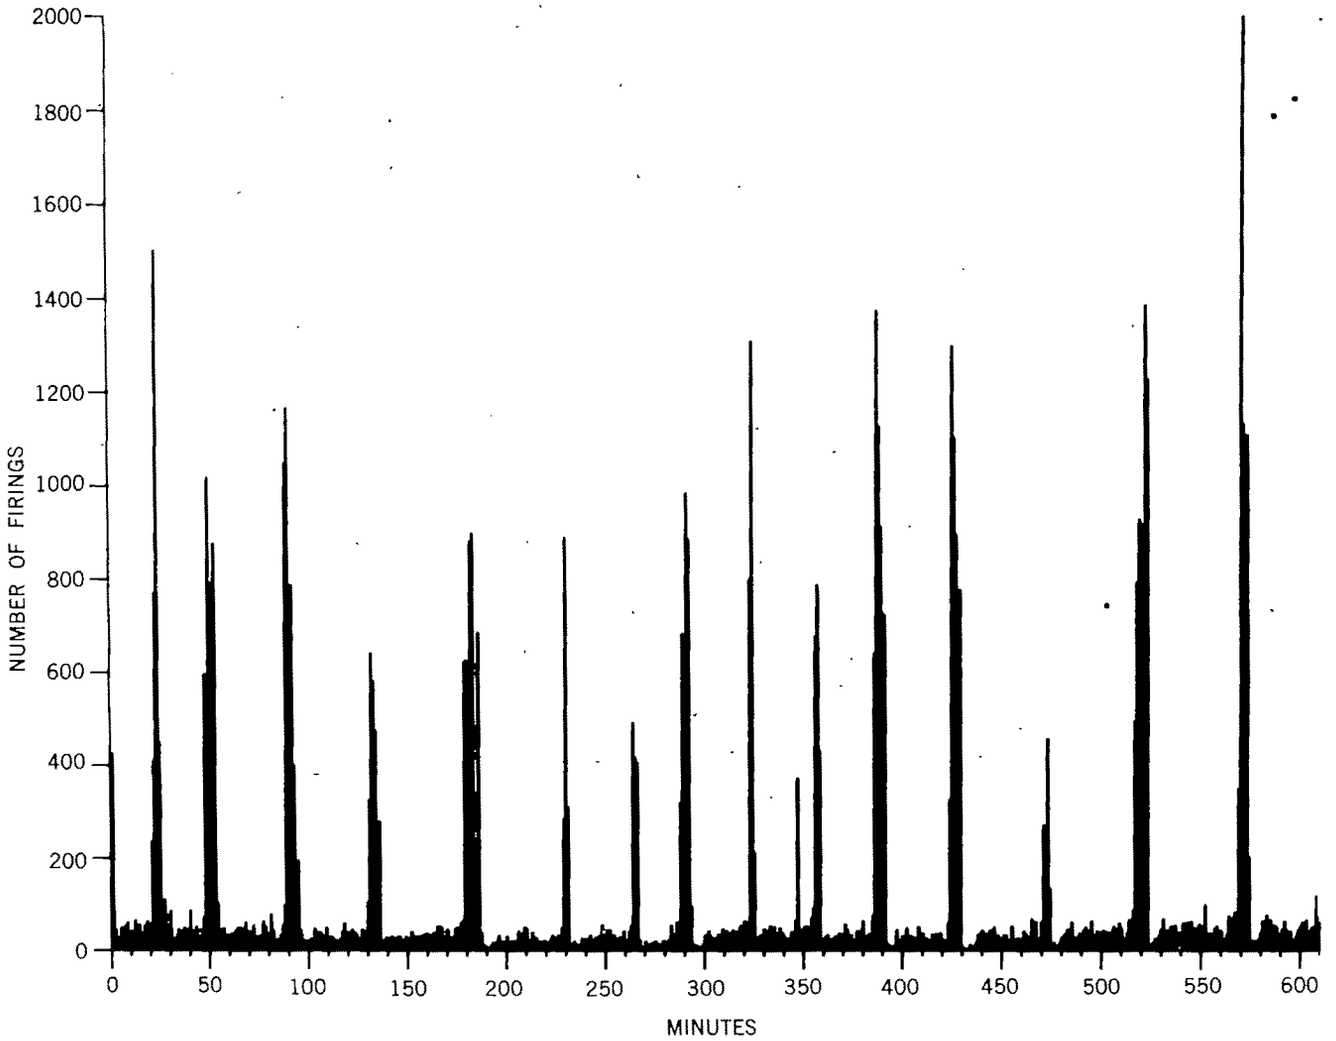
A direct experimental approach to the question of D state control has been made with cats by recording from individual neurons in many parts of the brain as the sleep cycle normally evolved. In this experimental paradigm, the frequency and pattern of extracellular action potentials, which are the signal units of nerve cells, are taken as indices of a cell's excitability; the influence of a recorded neuron upon other cells and that neuron's own control mechanism may also be inferred from the data. This method has the advantage of being relatively physiological since it does little to alter or damage the properties of the system under study. When cats are kept active at night, they will sleep under the necessary conditions of restraint during the daytime. The microelectrodes can then be stereotaxically directed at the brain stem and individual cell activity recorded for as long as 20 hours, allowing many successive sleep cycles to be studied (see figure 5).

The pontine brain stem control hypothesis has been tested in three ways at the level of single cells.

Selectivity criterion: which cells change rate most in D? We assumed that cells which showed pronounced alterations in discharge rate over the sleep cycle were more likely to be playing a controlling role than those showing minimal change. We further assumed that those cells having peaks of activity in phase with the D phase of the cycle were more likely to be specifically and actively involved in dreaming sleep state control than those with multiple peaks. We found that the giant cells of the pontine tegmentum concentrated their discharge in the D phase of sleep to a greater extent than any other group of neurons (27). They became our prime candidate for a generator function.

Tonic latency criterion: which cells change rate first in D onset? If the cells with positive discharge selectivity were driving the dreaming sleep phase of the sleep cycle, then their rates would be expected to increase in advance of the behavioral state change. Such phase leads might well be longer than those of the follower neurons under the control of the giant cells. The giant cells, when recorded over entire sleep cycles and through repeated sleep cycles, were found to change rate continuously (28). Significant rate increases occurred *as long as 5 minutes* before a desynchronized sleep phase. When the 2 minutes just prior to desynchronized sleep onset were studied, a rate increase in a pool of giant cells was observed 10 seconds before a similar increase in a pool of cerebral cortical neurons.

The rapidly accelerating limb of the giant cell activity curves at D sleep phase onset indicated that this was a time of maximal excitability change in this pool of neurons. The goodness of fit of the data by an exponential curve indicated that reexcitation within the pool might be superimposed upon disinhibition from without. The positive tonic latency indicated that the activation of the forebrain might be a consequence of activation of the brain stem but that the converse could not be the case.



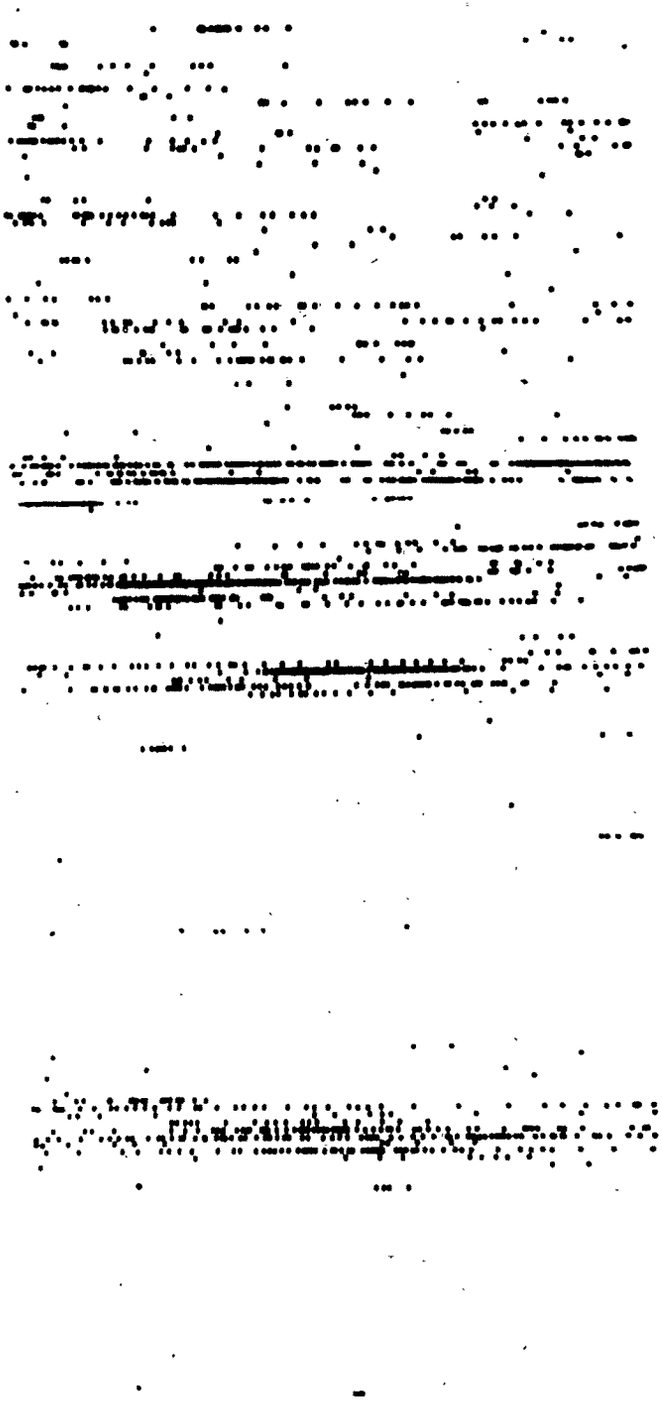
Phasic latency criterion: which cells fire before eye movements of D? Because of the proximity and direct projections to oculomotor neurons from giant cells, we tested the possibility that they might be generating the REMs so characteristic of the desynchronized phase of sleep by determining the time of occurrence of short-term rate increases by the giant cells in relation to eye movement onset. On the average, such rate increases were more prominent and anticipated eye movement by longer intervals than other brain stem neurons (29). Rate increases by presumed follower elements (in the posterolateral cerebral cortex) *followed* the eye movements by many milliseconds. It could therefore be concluded that the eye movements might be initiated by giant cells but could not be generated by cortical neurons. This finding practically wrecks the scanning hypothesis and strongly favors the idea that visual cortical events are determined by events in the oculomotor brain stem.

At this point we felt justified in concluding that the giant cells of the pontine tegmentum were critical output elements in a sleep cycle control mechanism. More particularly, we proposed that they might be generator elements for some of the tonic and phasic excitatory events in the desynchronized sleep phase of the cycles: most important to the activation-synthesis hypothesis of dreaming are the determination of EEG desynchronization (activation of the forebrain) and REMs (provision of forebrain with internally generated information). At the very least, we felt that we had found an important avenue to understanding sleep cycle control, since we could now examine the properties and possible mechanisms of giant cell excitability regulation. In this regard there are three additional points worthy of emphasis.

Periodicity criterion. Long-term recordings of giant cells revealed peaks of activity in phase with each full-blown desynchronized sleep episode (30) (see figure 6). Less prominent peaks were associated with abortive episodes and were rarely seen with no electrographic evidence of desynchronized sleep. Spectral analysis of these long-term data confirmed the impression of powerful periodicity in the discharge peaks, indicting that 1) sleep cycles are periodic, 2) underlying cell activity is probably even more so, and by definition, 3) cell excitability is under the control of a neurobiological clock. The possible mechanisms of excitability control are thus of great interest.

Phasic pattern criterion. The pattern of giant cell discharge within each D sleep episode indicated that classical pacemaker mechanisms are *not* involved in giant cell excitability regulation (31). Regular inter-

FIGURE 6
Discharge Activity of a Giant Cell Neuron Recorded over Multiple Sleep-Waking Cycles*



*Each peak corresponds to a desynchronized sleep episode, and a regular trend of discharge activity over a cycle is observable: a peak in desynchronized sleep; a rapid decline at the end of the desynchronized sleep episode; a trough, often associated with waking; a slow rise (in synchronized sleep and preceding all electrographic signs of desynchronized sleep); and an explosive acceleration at the onset of desynchronized sleep. Note also the extreme modulation of activity and the periodicity (30).

spike intervals were exceptional, indicating that the rate increases were not caused by endogenous membrane depolarizations. The tendency, rather, was for giant cells to discharge in intermittent, prolonged clusters of irregularly distributed spikes as if the cells were responding to excitatory postsynaptic potentials from other neurons (see figure 7). In our view, a likely source of much of this input, especially as the longer clusters developed, was other giant cells. Once other neurons were excited, feedback from them is to be expected. It also seemed likely that the clusters of giant cell discharge were causally related to the eye movement bursts of the D sleep phase.

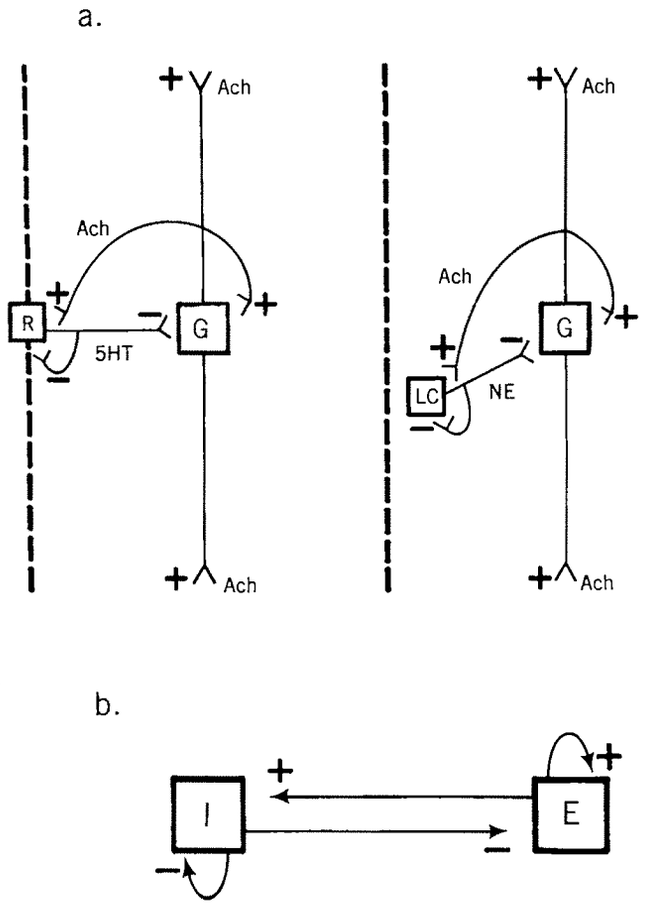
Reciprocal interaction criterion. If giant cell excitability change is not an intrinsic property of the giant cells, what other cell group might regulate it and in what way might that regulation be effected? Since all indices showed giant cells to discharge first in relation to both the tonic and phasic events of desynchronized sleep, we considered the possible contribution of inhibitory neurons. Since interneurons do not appear to exist in the giant cell fields, such cells should be discrete from but proximal to the giant cell. To be effective, projections should be abundant and should have inhibitory transmitter action upon the giant cells. Reciprocal rate changes during the sleep cycle are to be expected if such cells exist. We have discovered just such changes in a small number of unidentified cells in the region of the posterior locus coeruleus and the nucleus subcoeruleus (32). Not only is discharge concentration of these elements quantitatively inverse to those of the giant cells in the phases of the cycle, but their decelerating rate curve is the approximate mirror image of that of the giant cells

FIGURE 7
Temporal Clustering of Extracellularly Recorded Discharges of Cat Giant Cell Neurons During D Sleep*

*Each discharge is represented by a dot; the time sequence runs left to right and top to bottom, with each line 1 second in duration. The figure encompasses about 200 seconds of D sleep activity. Clustering is visible as closely spaced dots and, over longer durations, as "bands" of activity, some of which appear to occur rhythmically. Note the various durations of clusters and the presence of shorter duration clusters of activity within longer duration clusters. Clusters are delimited by periods of relative inactivity. Such sequences of giant cell neuronal activity are temporally associated with runs of eye movements and ponto-geniculo-occipital waves, and similar sequences of executive neuron discharges may represent the neuronal substrate of dream sequences in man (Hobson and McCarley, unpublished data).

at desynchronized sleep onset as seen in part C. We called such cells "D-off" cells to contrast their activity curves with those of the giant cells, prototypes of the "D-on" species of neurons. We do not know if the "D-off" cells are catecholaminergic but their location and discharge properties make this possible.

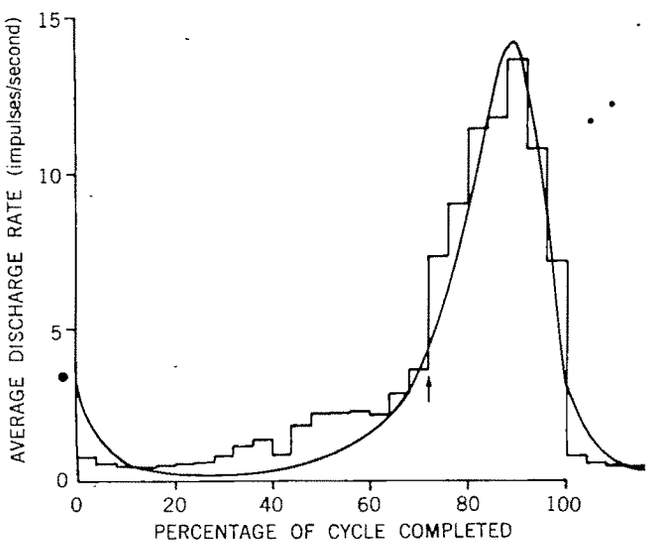
McGinty and associates (33) have found similar reciprocal rate changes in the dorsal raphe nucleus (DRN) neurons and we have recently confirmed this finding. The low regular rates of discharge by these cells in waking suggest a level-setting or pacemaker function. Their location and discharge properties are the same as those cells thought to be serotonergic on the basis of pharmacological experiments (34). Since both the LC and DRN are adjacent to and project to giant cells, and since giant cells receive abundant serotonergic and catecholaminergic endings, we thought that the mutual interconnections of these D-on and D-off cells could form a substrate for reciprocal interaction which regulated sleep cycle oscillation (30).



A MODEL FOR A BRAIN STEM SLEEP CYCLE OSCILLATOR

Restricting attention to within-sleep changes, we constructed a physiological model that bears a striking resemblance to the a priori schema derived from Cajal (see figure 8, top portion). Most of the connections have been demonstrated but many of the synaptic assumptions are as yet unproven physiologically. In addition to being explanatory, the model suggests experiments, particularly those employing pharmacological methods, the results of which will lead to its future modification. Since the LC, DRN, and giant cell groups are chemically differentiated, we deduced that their action and interaction may involve specific neurotransmitters.

In preliminary tests of the model, we have found that microinjection of the cholinomimetic substance carbachol into the giant cell zone not only gives more potent desynchronized sleep phase enhancement than injections into the adjacent tegmental fields but simultaneously activates giant cells. The results also indicate that an opposite effect is obtained at locus coeruleus sites (as if an inhibitory cell group were being activated). We have not yet tested this last hypothesis directly, but the LC cells do resume firing before the end of D sleep. We assume that as FTG excitation declines and LC inhibition grows, the cycle ends. In the decerebrate cat, physostigmine-induced D episodes are associated with activation of neurons in the giant cell and suppression of firing by cells in the LC and DRN (35).

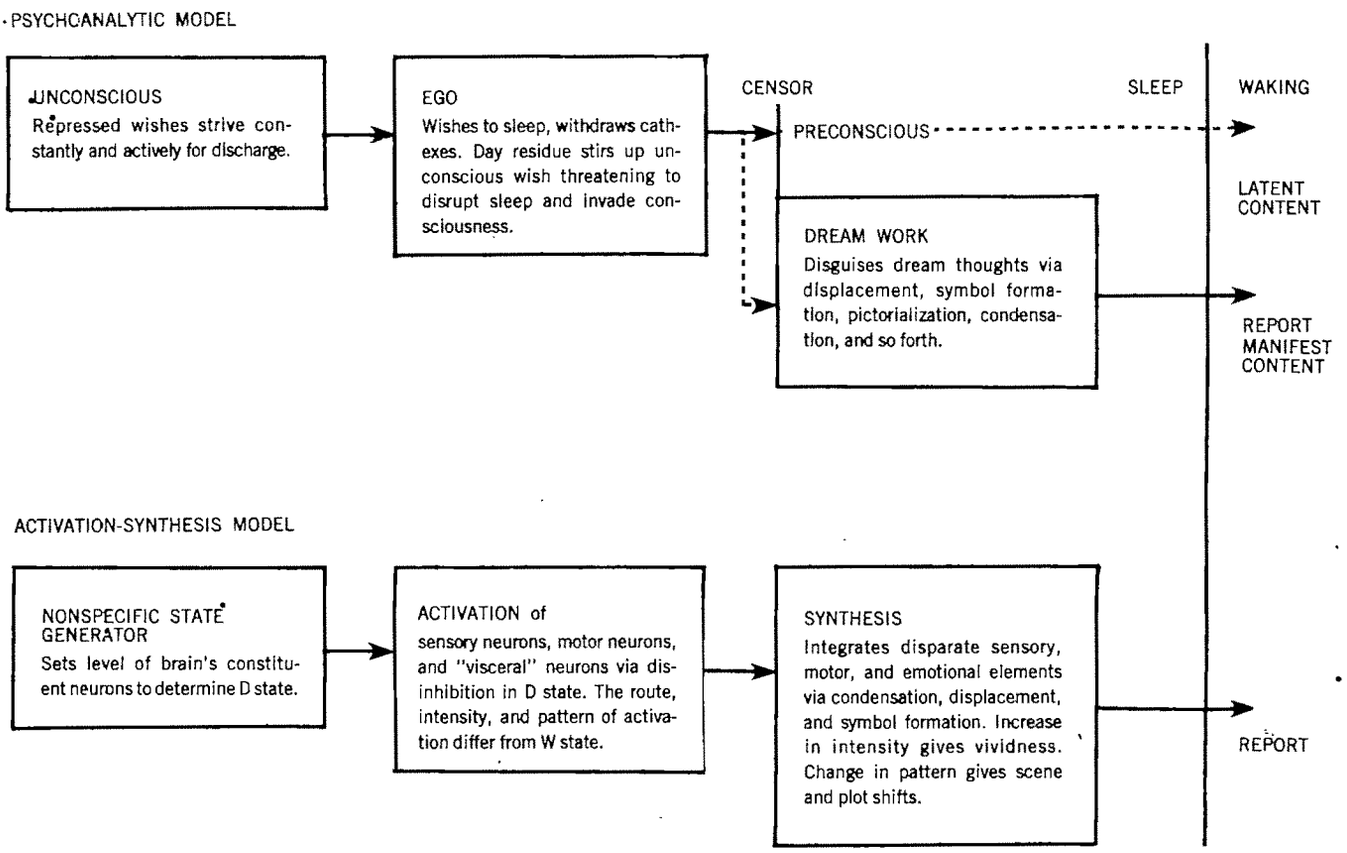


The physiological model can be reduced to a simple unit susceptible to mathematical analysis (see figure 8, bottom portion). Cell group E (giant cell) and cell group I (raphe and/or LC) are assumed to be mutually interconnected; cell group E is excitatory to itself and to group I, which inhibits itself and group E. Growth of

FIGURE 8
Reciprocal Interaction Model of Generator Process*

*Physiological models used to organize and interpret results of pharmacological experiments on desynchronized sleep. The G cells are seen as executive elements; they excite with and are excited by acetylcholine (Ach). They interact reciprocally with two aminergic cell groups, the LC and raphe (R), which utilize norepinephrine (NE) and serotonin (5HT) respectively. Both amines are hypothesized to be inhibitory to the G cells. D sleep will therefore be enhanced by increasing G cell excitability, and this can occur by either adding cholinergic drive or subtracting aminergic inhibition. Conversely, D sleep will be suppressed by subtracting cholinergic drive or by adding aminergic inhibition.
Formal reduction of the elements in the top portion of the figure yields the general model of reciprocal interaction, of inhibitory (I,-) and excitatory (E, +) populations, each of which contains a self-loop as well as a projection to the other set. The resulting oscillation of activity in the two sets can be mathematically described by the Lotka-Volterra equations.

FIGURE 9
Time Course of Giant Cell Activity over the Sleep Cycle*



*The histogram shows the average discharge level (impulses/second) of a giant cell neuron over 12 sleep-waking cycles, each normalized to constant duration. The cycle begins and ends with the end of a desynchronized sleep period. The arrow indicates the average time of D sleep onset. The smooth curve is derived from a mathematical model of sleep cycle control and shows a good fit to the experimental data. The probability of obtaining dream-like mentation reports might be expected to show the same trajectory as these curves (30). Reprinted by permission from *Science*, volume 189, pages 58-60, July 4, 1975. Copyright 1975 by the American Association for the Advancement of Science.

activity in one group occurs at the expense of growth in the other, and vice versa. As such the cell groups are analogous to two populations, prey and predator, whose interaction can be described by a set of nonlinear differential equations, the Lotka-Volterra equations (30). As shown in figure 9, the time course of activity of cell group E closely resembles that predicted by these equations. It is now possible to plot the activity curves of cell group I and compare the actual data with the curves predicted by the model. The phase lag between the reciprocal cycles remains to be explained and the previously noted fact that cycle length is proportional to brain size suggests that a distance factor may be at work. The distance between the two cell fields could be such a factor through its determination of protein transport time. Assuming an average LC-FTG internuclear distance of 2.5 mm and a fast protein transport time of 96 mm/day, a period length of about 35 minutes is predicted for the cat. This figure is within limits normal for that species. Another possible substrate for the long, size-dependent time constant of the cycle is the recently discovered class of long-duration postsynaptic transmitter actions (36) that may be mediated by second messengers such as cyclic AMP (37). Since the cyclic nucleotides activate protein kinases, the metabolic activity of the neuron, including the synthesis of neurotransmitters, can be linked to and entrained by membrane events.

An important point is that the mathematical model parallels, but is not identical to, the physiological model. This means that even if the specific assumptions about physiological interaction are incorrect, the mathematical model may be viable and useful in another system—for example, the coupling of the circadian and ultradian oscillators (14) or, at another level of analysis, in a molecular system. This is particularly important to keep in mind since it is also at the molecular level that time constant elements necessary to explain the long periodicity of the sleep-dream cycle may be found.

FIGURE 10
Two Models of the Dream Process*

*In the psychoanalytic model the motive force of the process is the dynamically repressed unconscious wish that is released from control in sleep. The dream thoughts that emerge threaten consciousness and sleep; they are deterred by the censor. The "dream work" transforms the unconscious wish by the processes that are listed. The product, or manifest content, that becomes conscious thus contains only disguised elements of the original (latent) dream thoughts.
The activation-synthesis model is designed to contrast activation-synthesis theory with the guardian-censorship theory illustrated in the top portion of this figure. The motive force of the process is seen to be nonspecific neural energy or excitation hypothesized to arise from a nonspecific generator. This excitation affects the component systems of the forebrain represented in the upper box: sensory systems generate scene frames, structural fragments, and qualitative features; cognitive systems generate ideas that may be conscious (day residue thoughts) or unconscious (instinctually determined); emotion is also generated at this first stage. The dream report, easily obtainable if a state change to waking occurs, is seen as an accurate reflection of the integrated product of disparate, internally generated elements.

PSYCHOLOGICAL IMPLICATIONS OF THE CELLULAR NEUROPHYSIOLOGY OF DREAM SLEEP GENERATION

Hallucinoid dreaming is regarded as the psychological concomitant of D sleep. Brain activity in the D state has been analyzed to account for activation of the forebrain, occlusion of sensory input, blockade of motor output at the spinal cord level, and the generation of information within the system. The evidence that the pontine brain stem contains a clock-trigger mechanism that contributes to activation of the forebrain, occlusion of sensory input, and the generation of internal information has been reviewed. The periodicity of the triggering mechanism is hypothesized to be a function of reciprocal interaction of reciprocally connected, chemically coded cell groups in the pontine brain stem.

The psychological implications of this model, which we call the activation-synthesis hypothesis of the dream process (schematically represented in figure 10), contrast sharply with many tenets of the dream theory provided by psychoanalysis (also represented in figure 10) in the following ways:

1. *The primary motivating force for dreaming* is not psychological but physiological since the time of occurrence and duration of dreaming sleep are quite constant, suggesting a preprogrammed, neurally determined genesis. In fact, the neural mechanisms involved can now be precisely specified. This conclusion does not, of course, mean that dreams are not also psychological events; nor does it imply that they are without psychological meaning or function. But it does imply that the process is much more basic than the psychodynamically determined, evanescent, "guardian of sleep" process that Freud had imagined it to be; and it casts serious doubt upon the exclusively psychological significance attached to both the occurrence and quality of dreams.

2. *Specific stimuli for the dream imagery* appear to

arise intracerebrally but from the pontine brain stem and not in cognitive areas of the cerebrum. These stimuli, whose generation appears to depend upon a largely random or reflex process, may provide spatially specific information which can be used in constructing dream imagery; but the unusual intensity, intermittency, and velocity of the eye movements may also contribute to features of the dream experience which are formally bizarre and have been interpreted as defensive by psychoanalysis. Thus such features as scene shifts, time compression, personal condensations, splitting, and symbol formation may be directly isomorphic with the state of the nervous system during dreaming sleep. In other words, the forebrain may be making the best of a bad job in producing even partially coherent dream imagery from the relatively noisy signals sent up to it from the brain stem.

The dream process is thus seen as having its origin in sensorimotor systems, with little or no primary ideational, volitional, or emotional content. This concept is markedly different from that of the "dream thoughts" or wishes seen by Freud as the primary stimulus for the dream. The sensorimotor stimuli are viewed as possibly providing a frame into which ideational, volitional, or emotional content may be projected to form the integrated dream image, but this frame is itself conflict free. Thus both the major energetic drive for the dream process and the specific primary stimulus of the dream content are genotypically determined and therefore conflict free in the specifically psychodynamic sense of the term.

3. *The elaboration of the brain stem stimulus* by the perceptual, conceptual, and emotional structures of the forebrain is viewed as primarily a synthetic constructive process, rather than a distorting one as Freud presumed. Best fits to the relative inchoate and incomplete data provided by the primary stimuli are called up from memory, the access to which is facilitated during dreaming sleep. The brain, in the dreaming sleep state, is thus likened to a computer searching its addresses for key words. Rather than indicating a need for disguise, this fitting of phenotypic experiential data to genotypic stimuli is seen as the major basis of the "bizarre" formal qualities of dream mentation. There is, therefore, no need to postulate either a censor or an information degrading process working at the censor's behest. The dream content elaborated by the forebrain may include conflictually charged memories, but even this aspect of dream construction is seen as synthetic and transparent rather than degradative and opaque.

4. *With respect to the forgetting of dreams*, the normally poor recall is seen principally to reflect a state-dependent amnesia, since a carefully effected state change, to waking, may produce abundant recall even of highly charged dream material. There is thus no need to invoke repression to account for the forgetting of dreams. This hypothesis is appealingly economical, and in the light of the reciprocal interaction hypothesis dream amnesia can now be modeled in a testable way as the result of a different balance between cholinergic and aminergic neuronal activity and the resulting effects on second messengers and macromolecules (5). Among its other surprising gifts to psychophysiology, dreaming sleep may thus also provide a biological model for the study of memory, and a functional role for dreaming sleep in promoting some aspect of the learning process is suggested.

SUMMARY AND CONCLUSIONS

Assuming that isomorphism, or identity of form, must characterize the simultaneous physiological and psychological events during dreaming, we have reviewed the general and cellular neurophysiology of dreaming sleep in search of new ways of accounting for some of the formal aspects of dream psychology. We have noted that the occurrence of dreaming depends upon the periodic activation of the forebrain during sleep. We have hypothesized that the activated forebrain synthesizes the dreams by fitting experiential data to information endogenously and automatically generated by reticular, vestibular, and oculomotor neurons in the pontine brain stem. A specific physiological and mathematical model of the pontine generator, based upon single cell recording studies in cats, is described: the model posits reciprocal interaction between inhibitory aminergic (level-setting) and excitatory cholinergic (generator) neurons.

Some of the "bizarre" formal features of the dream may directly reflect the properties of the brain stem neuronal generator mechanism. The physiological features of the generator mechanisms and their corresponding psychological implications include the following: the automaticity and periodicity of activation indicate a metabolically determined, conflict-free energetics of the dream process; the random but specific nature of the generator signals could provide abnormally sequenced and shaped, but spatiotemporally specific, frames for dream imagery; and the clustering of runs of generator signals might constitute timemarks for dream subplots and scene changes. Further, the activation by generator neurons of diffuse postsynaptic forebrain elements in multiple parallel channels might account for the disparate sensory, motor, and emotional elements that contribute to the "bizarreness" of dreams; the suppression of motor output and sensory input simultaneous with central activation of both sensory and motor patterns could assure the maintenance of sleep in the face of massive central excitation of the brain; and the change in the ratio of neurotransmitters affecting forebrain neurons might account for dream amnesia and indicate a state-dependent alteration of neural plasticity, with implications for the learning process.

Psychiatry, the Healthy Invalid

BY JEROME D. FRANK, M.D.

The author examines the reasons that have been offered in support of a pessimistic appraisal of psychiatry's future. The consequences for psychiatry of increasingly detailed knowledge of the interaction of psychological and physiological processes are emphasized, and the author concludes that psychiatry will continue to play a dominant role in its traditional domain and an increasing role in the study and treatment of medical and surgical illness. Thus, although the field is in a transition period, it is certainly not moribund.

THE IMPRESSION is abroad that psychiatry is seriously ill, if not actually at death's door. The thesis of this paper is that, although psychiatry is indeed experiencing distressing symptoms, they are not dangerous. Rather, most are analogous to the growing pains that accompany maturation.

Pessimists both within and without the profession support their judgment by enumerating various signs of illness. High on the list appears to be a widespread public disenchantment with psychiatry. It has become abundantly clear, for example, that psychiatrists do not have the answers to race relations, truancy, criminality, and war, and it is demonstrated repeatedly in courts of law that psychiatrists cannot agree on the mental state and degree of responsibility of defendants. Another criticism is that psychiatrists, in the guise of diagnosing and treating the mentally ill, are actually agents of social control, imprisoning deviants in mental hospitals by labeling them "ill" and then punishing them with electroconvulsive treatment, seclusion, and the like under the label of therapy. This accusation, most recently dramatized in the film "One Flew Over the Cuckoo's Nest," has led to a blizzard of lawsuits and judicial decisions concerning patients' rights.

The prophets of psychiatry's early demise also assert that psychotherapy conducted by psychiatrists is not cost-effective and that medical training does not provide any particular expertise in the use of psychotherapy. As a result, many people who previously sought psychiatric aid are flocking to nonmedical professionals such as psychologists, social workers, and mental health counselors, as well as to charismatic leaders who have developed their own therapeutic cults outside the boundaries of any profession.

Another development interpreted as a sign that psychiatry is in bad shape is the progressive withdrawal of public support, reflected, for example, in the phasing out of federal financing of psychiatric residency training programs, as a result of which the number of residents in training has been on a virtual plateau since 1972 and may be decreasing slightly. At the same time, the number of medical students has increased, so the proportion of medical school graduates who become psychiatrists has declined from about 10.5% to 9% (1).

A final apparently ominous sign is related to the rapidly increasing knowledge of biochemical and neurophysiological components of psychoses. It is claimed that nonpsychiatric physicians will increasingly take over the treatment of such illnesses, as they have done with the psychoses of pellagra and general paralysis of the insane.

Publicly discredited, harassed by the legal profession, suffering progressive shrinkage of federal support and of new recruits, and facing increasing competition from both nonmedical therapists and nonpsychiatric physicians, psychiatry would indeed appear to be in a parlous state.

THE ILLS OF PSYCHIATRY IN HISTORICAL PERSPECTIVE

In attempting to evaluate the validity of the dire diagnosis of psychiatry's state, it may be helpful to look briefly at the historical development of the current predicament. About two centuries ago psychiatry emerged as a medical specialty whose function was the care and treatment of the hospitalized insane. Psychiatry did not share in the spectacular gains of knowledge brought about by cellular pathology and the germ theory of disease and therefore became increasingly separated from the mainstream of medicine—mental hospitals became warehouses for segregating the mentally ill and havens for the less successful physicians. Public indifference to these hospitals permitted the growth of abuses such as ignoring patients' rights and failing to provide treatment. In the United States, reformist efforts to promote humane treatment of the mentally ill, led primarily by laymen, temporarily mitigated these abuses, but they were soon overwhelmed by the massive influx of immigrants from different cultural back-

Adapted from the first O. Spurgeon English Honorary Lecture, Temple University, Philadelphia, Pa., March 18, 1976.

Dr. Frank is Professor Emeritus of Psychiatry, the Johns Hopkins University School of Medicine, Henry Phipps Psychiatric Clinic, 601 North Broadway, Baltimore, Md. 21205.

grounds. Most public mental hospitals reverted to human warehouses. Despite spasms of temporary improvement following public exposés, this deplorable state of affairs has only recently begun to change as a result of the introduction of antipsychotic medications and the development of community mental health programs.

In the meanwhile, toward the close of the nineteenth century, Sigmund Freud, on the basis of astute clinical observations, promulgated an intellectually dazzling, aesthetically appealing, and endlessly fascinating conceptualization of mental illness. Psychoanalysis created a brand new field of knowledge and therapy out of what had previously been chaos and demonstrated that a host of hitherto inexplicable symptoms and signs such as functional paralyses and anesthesias, compulsions, phobias, and obsessions could be treated psychologically. As a result, many patients with these complaints, especially the more educated and affluent, flocked to psychoanalysts for relief. The status, as well as the income, of psychoanalysts soared and, because of its intellectual challenges, psychoanalysis soon attracted the best minds in the field.

Psychoanalytic theories emphasized the role of stressful interactions with other persons in the production of neurotic symptoms. Initially, emphasis was on traumatic experiences within the family, which led to concern with child-rearing practices and then gradually to interest in the pathogenic role of all social stresses. Concomitantly, psychoanalytic theory expanded into a general theory of human nature. These developments created incentives for psychoanalysts to study and try to ameliorate all social problems. The high regard in which psychoanalysts were held, especially by the intelligentsia, contributed to the grandiose delusion of some that application of psychoanalytic principles could cure, or at least ameliorate, practically all social ills. Psychoanalysts offered their services as policy advisors to political leaders, without any first-hand knowledge of the problems to which they offered solutions. An extreme example was the assertion that the way to bring about world peace was to require that all political leaders be psychoanalyzed. Understandably, the credibility of psychoanalysts suffered.

The large number of psychiatric casualties of World War II, in conjunction with the overly optimistic evaluation of psychiatry by the public, led the federal government to provide lavish support for psychiatric training, research, and practice, resulting in a more than five-fold increase since 1948 in the number of psychiatrists. In the last decade the increase has been 51%—double that of physicians in general (1).

The discovery that bodily symptoms were often related to emotional states soon emboldened psychoanalysts to turn their attention to psychological aspects of medical illnesses, and by the 1930s they had established a firm beachhead in this area. The initial hope of relating specific psychodynamic conflicts to specific diseases remains to be fully realized, but psychiatrists did establish their usefulness to their medical colleagues, as reflected by the rapid spread of psychiatric liaison services.

An evaluation of the current criticisms of psychiatry in the light of this historical review suggests that the charges of grandiosity and arrogance were partly warranted in the past but have become increasingly ill-founded. Psychiatrists have become appropriately more cautious about hospitalizing mental patients involuntarily and have taken the lead in efforts to make mental hospitals genuine treatment centers and to promote community mental health care programs. They have also become more careful to inform themselves about the social and political problems for which they offer psychiatric insights and more modest about their contributions. In so doing, they are gradually regaining credibility.

The malpractice suits and administrative regulations that currently threaten to strangle all medical practice will almost certainly subside to an appropriate level as their damaging consequences for patient care and treatment become increasingly apparent.

The reduction of funds for psychiatric residency programs could be less a reflection of public disenchantment with psychiatry than a recognition that the specialty no longer needs and should not continue to receive special care and feeding. Psychiatry is now sufficiently well established for its training programs to be put on the same financial footing as those of the other branches of medicine.

Although members of other helping professions often can do as good a job of psychotherapy as psychiatrists, the fact is that there is no evidence of slackening of demands for psychotherapy by psychiatrists. The healing aura that surrounds the medical degree, the psychiatrist's indoctrination into the assumption of full responsibility for patients, and his residual familiarity with disorders of the body all assure that the psychotherapeutic services of psychiatrists will be sought for some time to come.

The prediction that nonpsychiatric physicians will take over the treatment of psychoses seems highly unlikely. Psychotics are uncomfortable patients to deal with, and most physicians are only too happy to relinquish their care to psychiatrists. Moreover, pellagra and paresis have a single, easily eradicated organic cause. There is ample evidence that the great majority of psychoses, including the group of disorders called schizophrenia, have multiple causes and that proper management requires continuing attention to their psychological aspects. More fundamentally, the assumption that any disease in which bodily disorders play an important role is best treated exclusively by internists or surgeons implies a dualistic view of human functioning that is increasingly untenable.

Interactions of psychological and bodily processes form a seamless web; this is as true of medical and surgical conditions as of psychiatric ones. This recognition is the result of the explosive advances in detailed quantitative knowledge of the relationships of

so-called mental and bodily phenomena made possible by new instrumentation and the use of computers for multivariate data analysis. Among the new instruments are the electron microscope, fluorescent dyes that permit visualization of neuronal tracts and cells containing different neurotransmitters, microassays of circulating hormones, and computer analyses of EEG.

RESEARCH ADVANCES IN MIND-BODY INTERACTIONS

A few representative examples of newer findings concerning the interaction of psychic and bodily processes may indicate the variety and promise of advances in the area of mind-body interactions. I have grouped the material in four categories: clinical research in certain diseases, harmful and beneficial psychological effects of medical and surgical procedures, interactions of psychological states with hormones and immune responses, and some relations of brain functions to consciousness.

Clinical Research Studies

Considering first advances in the specification of the relation of bodily and psychic states, an intriguing example at the clinical level is reversible somatotropin deficiency, or psychosocial dwarfism—a lag in growth and maturation found in boys who have been raised in a stressful home environment; they promptly start to grow when removed from the home. A likely explanation is that production of the pituitary growth hormone increases during sleep, suggesting that the child's failure to grow may be related in part to inability to sleep in the disturbed home (2).

That mental states may affect the course of infectious diseases was shown by studies of the relation of depression to delayed convalescence in brucellosis and influenza (3). The influenza study was prospective and therefore more conclusive. All the personnel of a military installation were given a paper-and-pencil test of depression before an anticipated outbreak of influenza. Those who became ill were divided into two groups: those who recovered in an average of about a week and those who continued to complain for at least three weeks. The severity of the initial attack, judged by a variety of tests, was the same for both groups, but the slow recoverers had scored significantly higher on the scale of depression.

Since symptoms of influenza resemble those of depression (lassitude, weakness, vague somatic complaints), this finding could be explained by the assumption that patients and doctors were mistaking depression for delayed convalescence. To exclude this possibility, a strictly objective criterion of improvement would be needed. One such carefully designed study exists, conducted by three clergymen who were also trained psychologists. The criterion was speed of healing of a detached retina. Patients were interviewed before the operation and their "acceptance" was rated on a paper-and-pencil scale that included such items as trust in the surgeon, optimism about outcome, confidence in ability to cope regardless of outcome, and preparedness to accept the bad with the good. Speed of healing was rated by the surgeon independently and without knowledge of the test scores. A significant correlation was obtained between acceptance and speed of healing ($p<.001$), leading the authors to conclude that "high acceptance and rapid healing occur . . . when the patient has faith in the healer, his methods of healing, and feels that these methods are relevant to the cause of his illness . . . the person seeking to help the slow healer . . . should focus primarily on what variables enhance or destroy the patient's attitude of expectant faith" (4, p. 140).

If psychological states are related to susceptibility to infection and speed of healing, it should not come as a surprise that they apparently also affect the course of cancer. Western medicine has conceptualized cancer as an invasion of the body from inside by cells that have gone wild, and treatment consists of an effort to remove or destroy them by surgery, radiation, or drugs. The outcome of this struggle is determined by whether the cancer cells or the destructive agents are stronger. The patient is simply the arena in which the battle is fought—he cannot influence the outcome. However, this theory cannot explain spontaneous remissions of definitely diagnosed cancer. Two surgeons have accumulated 176 examples of such remissions from the literature but offer no explanation for them (5).

Recently, there has emerged the so-called surveillance theory of cancer, which offers a possible explanation for at least some of these spontaneous remissions and suggests additional therapeutic approaches. According to the surveillance theory, cancer cells are formed throughout life but are promptly detected and destroyed by the person's immune system. Clinical cancer appears when this system fails. Hence, factors that influence immunity, including psychic ones, are relevant to both the emergence and treatment of cancer.

What is the evidence in support of this hypothesis? First, an increasing number of studies have found that persons with a certain personality style are especially prone to cancer. Compared with matched healthy controls or those suffering from other illnesses, they repress or deny unpleasant affects such as depression, anxiety, and hostility (6). Under a facade of cheerfulness and self-confidence, they feel isolated and view life as a hard struggle. The finding that these chronically stressed persons may have heightened susceptibility to cancer is consistent with the relation of adrenal cortical activity to immunity, which I will consider presently.

The cancer patient's attitude toward life seems related to early life experiences that led him or her as a child to feel that close emotional relationships brought pain and destruction (7). This retrospective finding has

recently found indirect confirmation from a prospective study of male medical students who on entering medical school were given a battery of tests that included a rating scale of closeness to parents. Those subjects who had developed malignant tumors 10–20 years later were found to have scored significantly lower on this scale than controls matched by age and class who were in good health (8).

Psychological Effects of Medical and Surgical Treatments

As is suggested by the study of surgery for detached retina mentioned earlier, medical and surgical treatments have psychological repercussions that may significantly affect their outcomes. Two medical procedures with noxious psychological concomitants that warrant the attention of psychiatrists are hemodialysis for renal failure and intensive care treatment for coronary disease. That hemodialysis is enormously stressful emotionally is evidenced by a suicide rate of 6%, which is approximately 400 times greater than the overall incidence in the general population. This finding cries for more study of personality attributes of dialysis patients that predispose them to or protect them from such a tragic outcome, as well as methods for helping them to endure the strain. In this connection, it is striking that patients undergoing hemodialysis in hospitals have about 9 times the suicide rate of those receiving treatment in their own homes (9). An analogous finding emerges from the investigation of the treatment of acute myocardial infarction. Data are accumulating which indicate that the death rate at 28 days following the infarction is as high for patients treated in intensive care units as for those who remain at home (10). Apparently the psychologically damaging effects of being transferred to a hospital and, perhaps, of some of the procedures in the intensive care unit outweigh the benefits of the availability of equipment for monitoring cardiac function and combating ventricular fibrillation and cardiac arrest.

On the positive side, all medical and surgical procedures incorporate the beneficial psychological effects of the patient's belief in the physician's healing power. This is customarily labeled the placebo effect, an unfortunate term because it implies that the effect is illusory and based on deception. Investigations have shown that the patient's response to placebo results from a complex interaction between his momentary state, the physician, and other aspects of the situation (11). Overall, however, placebo is a powerful remedy. In fact, it can be argued that until this century the reputation of physicians rested primarily on the placebo effect because, with the exception of a few drugs such as quinine, digitalis, and morphine, most of the concoctions they administered were at worst toxic and at best pharmacologically inert (12).

Double-blind studies comparing placebo with active medication for the relief of subjective complaints have repeatedly found the effect of placebo to be about half that of the medication, regardless of the latter's pharmacological efficacy. For example, placebo is about half as effective a pain reliever as both propoxyphene HCl and morphine, although pharmacologically morphine is a much more powerful analgesic. Apparently, the doctor somehow conveys to the patient his knowledge of the potency of the active drug (13).

If medication can have powerful placebo effects, one would expect surgical operations to have even stronger ones. Compared with a person seeking medical treatment, the surgical patient is more apprehensive and is totally dependent on the surgeon—he literally places his life in the surgeon's hands. Furthermore, the operation is a single dramatic act that is expected to produce a prompt cure. This description applies especially to operations on the heart, so it should not come as a surprise that their psychological effects may account for much of their success. This was first suggested by the fact that approximately 40% of patients who underwent ligation of the internal mammary artery for relief of anginal pain experienced marked symptomatic relief, including reduced pain and increased exercise tolerance without ECG changes. Unfortunately, a sham operation produced identical results (14), so the procedure was abandoned; it has been superseded in recent years by coronary bypass, which is currently enjoying a widespread vogue. Its rationale is completely convincing: angina is caused by poor circulation to part of the heart muscle resulting from partial occlusion of a coronary artery and therefore can be cured by restoring the circulation through bypassing the diseased portion of the artery with a segment of vein.

The reported surgical results have been spectacular. About 90% of patients report reduction of symptoms and improved quality of life and about 75% also can tolerate more exercise without pain or ECG changes. It would appear absurd to question that this improvement is caused by better blood flow to the heart as the result of the bypass. Comparisons with patients receiving medical treatment, however, have raised questions as to how much benefit is actually due to improved cardiac circulation. When compared with a matched group of patients treated medically, patients given surgery showed no definite evidence of improvement in life expectancy (15). Furthermore, on an objective test of ventricular function, about 44% showed no change, 38% were actually worse, and only 18% showed some improvement (16). In short, although symptomatic improvement occurred in 90%, there was improvement in heart function in only about 20%; therefore, 70% improved in the face of an unchanged or further deteriorating heart muscle. Although the issue is currently controversial, a reasonable conclusion, especially in light of the earlier experience with ligation of the internal mammary, is that improvement in a significant proportion of patients is due to the psychological effects of the operation, especially the patient's expectant faith. This is powerfully reinforced by a convincing rationale according perfectly with the scientific Weltanschauung of our culture and a spec-

tacular procedure that involves stopping the patient's heart and then reviving him. In a sense, the surgeon kills the patient and brings him to life again. Few shamans can demonstrate equal healing power.

Neurochemical and Neurophysiological Studies

Findings in neurochemistry and neurophysiology create new potential clinical roles for psychiatrists in the treatment of patients whose emotional states may affect the course of their organic illness. Their full contribution, however, depends on the ability to elucidate the biochemical and physiological processes, especially in the central nervous system, that mediate the interactions between bodily and psychological states. It is in specifying these intermediate processes that progress, although still fragmentary, has been especially promising.

Findings from an extensive series of studies on the interaction of circulating norepinephrine and epinephrine with psychological stress may serve as examples. If army recruits with different levels of circulating hormones under stress are placed in a group for an extended period of time, the levels gradually cluster as if under the influence of emotional contagion. Another provocative finding is that recruits who have lost a mother in childhood show a much greater activity of the adrenal cortical system than those who have lost a father (17, 18). This accords well with findings in groups of working women that 1) circulating levels of blood cortisol are increased in depression and 2) loss of the mother before age 12 predisposes the child to depression as an adult (19).

The finding that stress during basic training, which is accompanied by a rise in circulating cortisol, increases the susceptibility of recruits to virus infections accords with the clinical material presented earlier on the relation of depression to delayed convalescence from influenza and to possible susceptibility to cancer. These are a few examples of a variety of findings that may be summed up as follows:

> Psychosocial processes influence the susceptibility to some infections, to some neoplastic processes and to some aspects of humoral and cell-mediated immune responses. These psychosocial effects may be related to hypothalamic activity . . . there is no single mediating factor. (20, p. 439)

Brain Function and States of Consciousness

One exciting area of research is the exploration of differences in function of the right and left cerebral hemispheres. As is now widely known, the left hemisphere mediates analytical thinking and language, and the right mediates intuitive processes and responses to patterns of stimuli. For example, activation, as indicated by suppression of alpha, occurs in the right cortex when a person hums the tune of a song, in the left when he recites the words, and in both when he sings the words (21). Such findings may explain why some intense aesthetic experiences and mystical states, which seem to be accompanied by predominantly right hemispheric activity, cannot be described in words.

A realm of research into bodily concomitants of states of consciousness that may have far-reaching therapeutic implications relates to Transcendental Meditation, Zen, Yoga, and other spiritual exercises originating in the mysterious East. Because of their origins, these techniques had little influence on Western research until advances in instrumentation made them legitimate objects of scientific research. Recent investigations have revealed that all forms of meditation produce changes in oxygen consumption, heart rate, blood pressure, skin resistance, and other physiological functions. These changes, collectively termed the relaxation response, are indistinguishable from those accompanying any state of relaxation coupled with focused attention (22). Whether various forms of meditation differ with respect to other bodily concomitants remains undetermined.

Biofeedback training as an adjunct to relaxation enables a person to gain extraordinarily precise control of body functions. Among promising clinical applications of relaxation and biofeedback are reduction of systolic blood pressure, correction of cardiac arrhythmias, relief of migraine, and control of fecal incontinence and of painful spasms of skeletal muscles. It is important to stress that biofeedback training is essentially a form of psychotherapy. As the Yogis have shown, the same results can be achieved without the gadgetry, and clinical success depends largely on the strength of the patient's motivation, which in turn is strongly influenced by his relationship with the trainer (23). Moreover, much of the therapeutic benefit of biofeedback training may be in its demonstration to the patient that he can control a bodily function, which heightens his self-confidence in other areas of his life.

States of relaxation are precursors of the more profound alterations of consciousness that occur with meditation. In these, persons may experience phenomena outside the realm of normal waking consciousness, including telepathic experiences, precognition, "out-of-the-body" experiences, and mystical revelations. This brings us to the edge of the seductive and fascinating realm of the paranormal, which is so studded with booby traps and quicksand that one must approach it with the greatest circumspection. A full consideration of the paranormal would lead us too far afield, but it can be said that an increasing number of studies of paranormal phenomena such as telepathy and healing by laying on of hands, which may be relevant to psychiatry, have been conducted by researchers of unquestionable integrity and meet acceptable standards of scientific validity (24–26).

More spectacular than the growth of specific information concerning the effect of psychic states on bodily functions is the exponential increase of detailed information on the effects of brain function on psychic states. Since reports of psychopharmacological studies currently provide much of the content of psychiatric journals, I will not attempt to review this bur-

geoning field. A single example will suffice: the discovery that drugs which decrease dopamine activity, such as phenothiazines, may be antipsychotic and drugs that promote dopamine activity, such as amphetamines, may be psychotomimetic, has triggered a veritable explosion of research guided by the hypothesis that schizophrenic symptoms may be related to a relative excess of dopamine-dependent neuronal activity. Although these studies have not yet produced irrefutable support for the hypothesis, the cumulative findings have been described as "compelling" (27).

DISCUSSION AND CONCLUSIONS

This sampling of studies illustrating the close interaction of mental and bodily processes sharply reveals the shortcomings of the dualistic view of human functioning, which has never solved the dilemma of conceptualizing just how mind and matter can influence each other. A possible way out, sufficient at least for present purposes, is provided by the so-called holistic view of the organism as an open system interacting with the environment through continuous exchanges of matter, energy, and information. Informational input affects biological processes and, if sufficiently intense and enduring or occurring early enough in life, can actually alter structure, as is suggested by psychosocial dwarfism. Biological changes, in turn, modify the individual's perceptions and behavior, providing new inputs into the system to complete the circle. The division of this process into causes and effects is essentially arbitrary, resulting from the need to categorize experience. All aspects of human functioning are simultaneously causes and effects of other aspects.

In holistic terms, health is defined as a system in harmony with itself and its environment. All diseases disrupt both the individual's internal integration and his interchanges with the environment at both biological and psychological levels. The task of the healer is to help to restore the harmony of this system within itself and in its interactions with the outer world.

Although most of the studies reported in this paper were conducted by psychiatrists, psychiatric training programs must be modified considerably if psychiatrists are to take full advantage of the new opportunities and challenges emerging from holistically oriented research. Current emphasis on psychological aspects of personal functioning must be balanced by more attention to neuroendocrine and other bodily processes, with particular emphasis on detailed studies of their interactions.

Psychiatrists should be in the best position to take advantage of these developments. In contrast to other medical researchers whose training stresses biological processes and to nonmedical researchers whose expertise lies in the understanding of psychological states, psychiatrists are concerned with both biological and psychological phenomena. They sit astride the mind-body boundary, as it were—a somewhat uncomfortable position, but one that is proving to be increasingly important for many aspects of medical research and practice. As the contributions of psychiatry in this realm increase, an increased interest by medical students in psychiatric residency training can be confidently predicted.

With respect to other aspects of psychiatry's future, the information I have presented supports the prognosis that psychiatry, rather than being on the verge of death, is about to enter a period of vigorous health. Psychiatrists are becoming more realistic, as befits the attainment of maturity. We are shedding some of our infantile omnipotence and our dependence on father figures like Sigmund Freud and Uncle Sam.

With respect to social and political problems, it is sobering to realize that human social behavior now looms as the greatest potential cause of disability and death. Uncontrolled breeding, reckless pollution of the biosphere, inadequate control of radioactive wastes from nuclear power plants, and resort to nuclear weapons in war or terrorism are forms of behavior that pose a far greater threat to humanity than naturally occurring pathogens and environmental disorders. While preserving a becoming modesty about their ability to resolve these dangers, psychiatrists should not allow their regret for earlier mistakes to prevent them from accepting the responsibility to contribute what they can. As students of maladaptive behavior and communication failures, with some experience in how to correct them, psychiatrists should be able to make significant, if limited, contributions toward the control of these man-made health hazards.

With respect to psychiatrists' traditional roles, although a growing number of the unhappy and alienated may gravitate to nonmedical helpers, there will be no dearth of individuals seeking psychiatric help. Further, it is not likely that nonpsychiatric physicians will be eager to assume responsibility for treatment of the severely mentally ill. In this connection, studies of population trends for the coming decade project an increase in schizophrenia of from 5% in whites aged 15–24 to 87% in nonwhites aged 25–34, so psychiatrists will not suffer from lack of patients (28).

While psychotherapy will continue to be our major form of treatment, our methods will expand to include behavioral techniques, biofeedback, and other psychobiological approaches. We will also continue to incorporate into our treatment armamentarium the growing body of information about psychoactive drugs, including their interaction with psychotherapy. In this connection, a recent study has found that some severely depressed patients respond to cognitively oriented psychotherapy alone at least as well as to imipramine (29), and a leading researcher in the treatment of schizophrenia has concluded that although the efficacy of pharmacotherapy is unquestionable, psychologically oriented forms of treatment are also necessary (30).

Finally, psychiatrists will contribute increasingly to the understanding and treatment of all disease, based

on expanding knowledge of interactions of mental states, behavior, and bodily processes as mediated by the nervous and endocrine systems.

All in all, while psychiatry may emerge from its current travails somewhat altered in appearance, its future is bright.

Social Discrediting of Psychiatry: The Protasis of Legal Disfranchisement

BY PARK ELLIOTT DIETZ, M.D., M.P.H.

The author believes that recent legal decisions against psychiatrists (including class action suits) have their genesis in writings by sociologists and other behavioral scientists, including psychiatrists, who have examined psychiatry in the context of social structure and social processes. The discrediting of the medical model could have been accomplished using theoretical assertions and research observations that had been published before 1940, but it did not occur until the human rights movement of the 1960s. The author reviews the assertions on which the discrediting of the medical model has been based. He stresses the distinction between the testing of a theory and the discrediting of a model and observes that the recent wholesale discrediting of psychiatry has relied less on theory testing than on polemical rhetoric and unwarranted extrapolation from empirical facts.

PSYCHIATRISTS HAVE become increasingly concerned about the proliferation of class action suits (such as *Wyatt v. Stickney* [1] and *Donaldson v. O'Connor* [2, 3]), legislative efforts (such as the Vasconcellos bill in the California Assembly [4]), and judicial decisions (such as in the Tarasoff case [5]) that would restrict their activities. No formal survey is needed to gauge psychiatrists' attitudes toward these developments. Most psychiatrists perceive such legal actions as unjustified attacks on psychiatry by attorneys and other outsiders, and they fear that the success of such actions will seriously handicap their efforts to care for patients.[1] Whether this perception is accurate does not concern us in this paper. The issue to be addressed here is the origin of this perception, which has an important influence on the professional identity and morale of many psychiatrists. This paper identifies sociological writings as a major source of both actions in mental health law and the perception that such actions comprise an attack. "Sociological writings" refers not only to the writings of sociologists, but also to a number of seminal works by psychiatrists, psychologists, and others who have examined psychiatry in the context of social structure and social processes.

The thesis of this paper is that the controversial actions in mental health, and psychiatrists' perceptions of these actions as an attack, are direct consequences of such sociological writings as those of Faris and Dunham, Edwin Lemert, Hollingshead and Redlich, Thomas Szasz, R.D. Laing, and Thomas Scheff. Empirical evidence for this thesis would lie in a study of the reading habits of attorneys, judges, legislators, and psychiatrists, and such a study has not been conducted (although some related evidence will be presented). But before the thesis is rejected out of hand for lack of sufficient evidence, it should be noted that Birnbaum (6) wrote the first article on the right to treatment while living in the company of sociologists as a research fellow in social relations at Harvard.

Insofar as mental health law advocates are motivated by humanitarian concerns, their major concern would seem to be that psychiatrists and psychiatric institutions may do harm to patients. One of our tasks, then, is to identify the intellectual roots of this concern. But the concern itself is not enough to produce social change. Illich (7) has recently argued that medicine in general does more harm than good, but it is safe to predict that his concern will not result in the closing of general hospitals or in attempts at legislative control of appendectomies or hemodialysis. The prerequisite for such change is a discrediting of the scientific and moral status of the profession. This prerequisite was fulfilled in the case of psychiatry by a host of writings

Presented as "A Sociological Perspective of the Siege of Psychiatry" at the seventh annual meeting of the American Academy of Psychiatry and the Law, San Francisco, Calif., October 21–24, 1976.

On the basis of this paper the author received the 1977 Wendell Muncie Award of the Maryland Association of Private Practicing Psychiatrists and the Maryland Psychiatric Society.

At the time this work was done, Dr. Dietz was Robert Wood Johnson Clinical Scholar, Assistant Resident and Fellow in Psychiatry and Behavioral Sciences, Ph.D. candidate in Social Relations, and Lecturer in Forensic Pathology, Johns Hopkins University, Baltimore, Md. He is now Fellow in Forensic Psychiatry and Robert Wood Johnson Clinical Scholar, University of Pennsylvania Center for Studies in Social-Legal Psychiatry. Address reprint requests to Dr. Dietz at the Forensic Psychiatry Clinic, 201B Piersol Building, Hospital of the University of Pennsylvania, Philadelphia, Pa. 19104.

This work was supported in part by a grant from the Robert Wood Johnson Foundation, Princeton, N.J., and by the Maryland Medical-Legal Foundation.

The opinions and conclusions expressed herein are those of the author and do not necessarily reflect the views of the Robert Wood Johnson Foundation or the Maryland Medical-Legal Foundation.

[1]For example, the theme of the meeting for which this paper was originally prepared was "Psychiatry Under Siege," a reference to this spate of legal actions.

condemning the use of the medical model[2] in psychiatry and implying that psychiatrists are malevolent creatures who have conspired to impose their world view on unsuspecting patients. Our basic task, then, is to identify the intellectual roots of the discrediting of the medical model in psychiatry and the discrediting of the moral character of psychiatrists.

DISCREDITING OF THE MEDICAL MODEL

A compendium of papers edited by Rose and published in 1955 (8) marked the end of an era in psychiatric sociology, the era in which conventional psychiatry was given the benefit of the doubt. The papers in this volume were not influenced by Lemert, Goffman, Szasz, Laing, and Scheff; they made no mention of the medical model, labeling theory, or the social control functions of psychiatry, all of which characterize later works. Bowman's paper (9) provides an extraordinary example of the extent to which the legitimacy of psychiatrists was taken for granted by sociologists of this era. Bowman argued that "just as the psychiatrist is competent to judge degrees of reality or unreality in the patient's interpretations, so the social scientist is equipped to determine the distortions of collective thought . . ." (9). Thus not only was the psychiatrist's role as the official judge of individual reality reaffirmed, but an attempt was made to adduce an analogous status to social scientists. This contrasts sharply with later writings, which contained the common theme that psychiatrists lack both the valid means and legitimate authority with which to judge reality.

As we shall see below, the discrediting of the medical model in psychiatry drew support from several theoretical assertions and research observations. It is noteworthy that the essence of this theory and research had already been published by 1940, but received little attention at the time. Eliot's paper on "Interactions of Psychiatric and Social Theory Prior to 1940" (10), also in the Rose volume, provides many examples of the kinds of assertions that later were used to discredit the medical model in psychiatry.

In the 1920s Eliot had written of "insanity" as a social situation rather than as a personal trait and had dealt with the cultural defining of "mental disease" situations and with the situational causes of "mental diseases." In the 1920s and 1930s Anton Boisen studied religious ideologies, ethical conflicts, and social life histories as factors of causation among institutionalized mental patients. In the 1920s Herbert Adolphus Miller coined the phrase "oppression psychosis" to describe typical reactions observed among minority groups. In 1930 Robert E. Park suggested that the study of cultural conflicts would shed light on functional disorders. In 1932 a session of the American Sociological Society's annual meeting was devoted to the cultural patterning of "psychotic" states peculiar to certain cultural areas. In the 1920s and 1930s Trigant Burrow, Lawrence Frank, and the essayists contributing to a volume edited by Schmalhausen all suggested that it is the civilized world which is insane and that we have no absolute criteria by which to differentiate mental illness from genius, sainthood, or vice. It was in the 1930s that Faris and Dunham and Lee Brooks documented ecological variations in the distribution of psychiatric disorders. In the 1930s Maurice Krout described the task of social psychiatry as the discovery and control of social causes of abnormal states. All of the examples in this paragraph are cited in Eliot's historical review, arbitrarily limited to the period 1915–1940; no doubt many earlier examples could be cited by a psychiatric historian.

Except for Faris and Dunham, the authors just cited are unfamiliar to psychiatrists today and are probably equally unfamiliar to mental health law advocates. Yet these same ideas, as they reemerged in the late 1950s and thereafter, were used to discredit the medical model. That they were not so used in the 1930s and 1940s is amply demonstrated by the success of Deutsch's 1937 book, *The Mentally Ill in America* (11), which is both a documentary of the unsatisfactory conditions provided for the mentally ill and a celebration of the emergence of the medical model in psychiatry.

As mentioned above, the discrediting of the medical model drew support from several theoretical assertions and research observations. The critical ones seem to be the following.

1. Interpersonal relationships are important in the pathogenesis of mental illness. This idea, which was common to Freud and any number of other psychiatric theorists as well as to the social theorists of the 1920s and 1930s, is written about today as though it were first discovered in the 1950s and 1960s, in the important family studies of Bateson and associates (12, 13) and Lidz and associates (14, 15).

2. The frequencies of different types of mental illness vary among socioeconomic classes. This observation, noted as early as 1856 (16) and well established in the 1930s, was replicated and expanded in the 1950s and 1960s, most notably by Hollingshead and Redlich (17) and by Srole and associates in the Midtown Manhattan study (18).

3. "Mental illness" is in the eye of the beholder. A relativistic concept of mental illness was put forward by a number of authors in the 1920s and 1930s, but it was not widely diffused until the publication of widely read books by Szasz (19) and Laing (20, 21) in the 1960s.

4. The chronicity of mental illness is ensured by the official labeling done by psychiatrists and the process of institutionalization occurring in mental hospitals.

[2]The phrase "the medical model" has a variety of referents in the sociological and psychiatric literatures. It is used in this paper to denote a predominantly organic ideology regarding the etiology, pathogenesis, and treatment of psychiatric disorders. Most of the writers whose works are cited in this paper have supposed or implied that this is the most prevalent ideology among psychiatrists; the fact that this has not been true for several decades has not lessened the impact of their writings.

Although it has long been obvious that facilities of the snake-pit variety could only serve to prolong the necessity for confinement, it was not until the 1950s that a major theory arose which suggested that any public or official categorization of a person as being "mentally ill" or "a mental patient" is a strong determinant of chronicity. This thesis grew from Lemert's effort (22) to account for the tendency of radicalism, criminality, alcoholism, mental disorder, and other conditions to progress or worsen. Lemert's work, which became widely known in the 1960s (e.g., through Becker [23]), has been extremely influential in contemporary sociology. Lemert is generally credited with constructing "labeling theory," which has been applied most extensively to psychiatric disorder by Scheff (24, 25). The pervasive effect of institutionalization on the lives of mental patients, rationalized largely by means of the medical metaphor, has been described most persuasively by Goffman (26).

These four propositions underlie the wholesale discrediting of the medical model in psychiatry. It is important to distinguish between the testing of a theory and the discrediting of a model. Theory testing relies upon logic and controlled observation, both of which have been applied to selected aspects of the medical model. Examples of logical and observational approaches include some of Szasz's original arguments in *The Myth of Mental Illness* (19), the derivative arguments of Albee (27, 28), and the empirical studies by Scheff (29), Mendel and Rapport (30), and Greenley (31).

In contrast, the wholesale discrediting with which we are here concerned relies upon polemical rhetoric and unwarranted extrapolation from empirical facts. Thus the first and second propositions, that interpersonal relationships are important in the pathogenesis of mental illness and that the frequencies of different types of mental illness vary among socioeconomic classes, are transmogrified into the assertion that the causes of mental illness are interpersonal and social, not medical.

Similarly, the third proposition, that "mental illness" is in the eye of the beholder (a proposition that reflects difficulties of diagnosis, cross-cultural and other variations in conceptualization, and the widely acknowledged difficulties of applying a disease model to personality disorders, sexual deviations, and situational adjustment reactions), is transmogrified into the assertion that mental illness (including schizophrenia and the affective disorders) is mythological and does not exist. The behaviors that under the medical model are called mental illness thus come to be seen as "problems in living" (19), "residual rule violations" (24), or "interpersonal disjunctions" (32, p. 67).

Finally, the fourth proposition, that the chronicity of mental illness is ensured by the official labeling done by psychiatrists and the process of institutionalization occurring in mental hospitals, is transmogrified into the assertion that psychiatrists and mental hospitals create, perpetuate, and exacerbate "mental illness."

These transmogrifications of the four propositions described above, if accepted, provide ample reason to reject the medical model in psychiatry. Taken together, they lead to the conclusion that social and interpersonal factors cause problems in living which, under the influence of psychiatrists and mental hospitals, are transformed into chronic "mental illnesses" such as "schizophrenia." This conclusion entails more than a scientific rejection of a theory; it constitutes what we have called the wholesale discrediting of the medical model.

MORAL DISCREDITING OF PSYCHIATRISTS

The discrediting of the moral character of psychiatrists has occurred much more abruptly. As illustrated previously, the legitimacy of psychiatrists was taken for granted for many years. As recently as 1966 it could be said that there were only a few sociologists "who tend to picture the psychiatrists' relationships with patients less as treatment than as work in the interest of the psychiatric establishment" (33). This has changed dramatically in the course of a decade, and there now are a great many sociologists and a large cohort of college graduates who view psychiatrists in an unfavorable light. Some of the better-known sources serving to discredit psychiatrists are as follows.

1. Hollingshead and Redlich's finding (17, pp. 253–303) that patients from lower socioeconimic classes are disproportionately more likely to receive organic therapies than are patients from upper socioeconomic classes, who are disproportionately more likely to be treated with psychotherapeutic methods. (These researchers specified that they did not believe that this was the result of deliberate policy.)
2. Goffman's observation (26, pp. 155–162) that the psychiatric case history is a dossier of discrediting facts and statements about the patient.
3. Kesey's fictional account (34) of the punitive use of electroconvulsive therapy and psychosurgery.
4. Szasz's claim (35) that "coercion and deceit are rampant in the legal and social uses of psychiatry—beginning with the pseudomedical definitions of mental illness, and ending with the tyrannical abuses of psychiatric power in cases of political and other offenses."
5. Laing's description (32, pp. 121–122) of the labeling of "schizophrenia" as a political event in which a person is inaugurated into a patient career "by the concerted action of a coalition (a 'conspiracy') of family, G.P., mental health officer, psychiatrists, nurses, psychiatric social workers, and often fellow patients."
6. The Medvedevs' account (36) of the use of psychiatry for political repression in the Soviet Union.
7. Halleck's thesis (37) that no aspect of psychiatry is politically neutral.
8. Torrey's description of preventive psychiatry as "the road to psychiatric fascism" (38).

Each of these eight sources casts doubt on the morality of psychiatric practice without even invoking the additional controversies posed by involuntary commitment. To these may be added the findings of Rosenhan's study (39), generally interpreted as indicating that psychiatrists cannot even distinguish the "sane" from the "insane." These assertions are not merely criticisms of psychiatrists; if accepted, they constitute a wholesale discrediting of psychiatrists. It is a discrediting that seems to have been anticipated by Davis (40), who in 1938 wrote a paper documenting the extraordinary bias of the mental hygiene movement (and, by implication, psychiatry) in promoting conventional values, a bias that could not be tolerated indefinitely from a profession with scientific pretensions. Although the above cited sources have been most influential, it should be noted that the discrediting process has been carried even further by a number of self-proclaimed radicals (41–43).

DISCUSSION

The basic task of identifying the intellectual roots of the discrediting of both the medical model in psychiatry and the moral character of psychiatrists having been fulfilled, it remains to be shown how these various assertions, which are herein claimed to be sociological, relate to the perception that psychiatry is under attack. In this regard there are three points to be made.

First and foremost is the fact that these assertions, their transmogrifications, and their radical extrapolations could only be accepted in a society characterized by a plurality of values and growing concern for human rights. Risking the fallacy of *cum hoc, propter hoc*, I suggest that the widespread acceptance of the discrediting views discussed above, many of which were shown to have been espoused in the 1920s and 1930s, did not occur until the 1960s because it was not until then that political activism and concern with human rights were sufficiently widespread. It is noteworthy that Rappeport (44) recently attributed major importance to activism and the human rights movement in the genesis of the mental health lawsuits with which we are concerned; this theme has been extensively developed by Stone (45). It is suggested here that the social climate of activism and concern for human rights also contributed indirectly to the propagation and success of these suits by fostering acceptance of the discrediting ideas that stripped psychiatry and mental institutions of their thin cloak of scientific and moral legitimacy.

Second, the discrediting sources described above have had a direct bearing on mental health lawsuits and are considered to be resource material by mental health lawyers. Hollingshead and Redlich (17) were cited in an amicus curiae brief in *Legion v. Weinberger* (46). Goffman (26) was cited in the respondent's brief in *O'Connor v. Donaldson* (47). Szasz (19, 35) was cited in the petitioner's brief in *Donaldson v. O'Connor* (48). Further, the Midtown Manhattan study (18) was cited in an amicus curiae brief in *Glassman v. New York Medical College* (49). The three-volume book *Legal Rights of the Mentally Handicapped*, edited by Bruce Ennis and Paul Friedman under the auspices of the Practising Law Institute and the Mental Health Law Project (50), is a unique sourcebook of materials on mental health law. The annotated bibliography of this sourcebook includes many of the discrediting sources described above, namely, Goffman (26), Halleck (37), Kesey (34), Laing (20, 32), Rosenhan (39), Scheff (24), Szasz (19, 35), and papers from the Radical Therapist Collective (41), as well as a variety of discrediting sources not mentioned above.

Finally, the third way in which the discrediting assertions reviewed above have contributed to the perception that psychiatry is under attack is that they have become inextricably linked to those legal actions which pose practical problems for psychiatrists. McGarry (51) and Rappeport (44) have noted that the optimism of psychiatrists and administrators in the early days of the right-to-treatment lawsuits was short-lived, for it soon became clear that the means by which judicially mandated reforms might be implemented were not forthcoming. Thus there developed what McGarry has called "The Holy Legal War Against State-Hospital Psychiatry" (51) and what Rappeport has called the "belegaled" state of contemporary psychiatry (44).

Although it is too early to judge adequately the effects upon our patients, there are psychiatrists who believe, as I do, that sociological criticisms and mental health legal actions will have a net beneficial effect on patient care. Nonetheless, it seems clear that a substantial proportion of the psychiatric community has an understandable disdain for the discrediting and disfranchisement described in this paper. To the injuries of increased malpractice hazards, expensive and time-consuming paperwork and court appearances, and increasing limitation of the discretionary power of psychiatrists have been coupled the insults of scientific and moral discrediting. It is no wonder that psychiatrists perceive themselves as being under attack in an era in which their discreditors are cited as authority in briefs for the courts.

Emotional Causes of Sudden Death

BY JOEL E. DIMSDALE, M.D.

The author reviews concepts important to understanding the emotional causes of sudden death, which occurs in the psychological setting of hopelessness, powerlessness, and intense emotions. The cardiovascular system responds to stress in a way that makes sudden death more likely. Studies pertinent to the effect of stress on blood pressure and arrhythmia in animals and man indicate that sudden death as a response to stress can occur only when certain factors are present simultaneously. Collaboration between psychiatrists and cardiologists is necessary for further progress in this field.

THE RELATIONSHIP of emotion to sudden death is an important area because of the widespread occurrence of sudden death and because of persistent theories about the role of emotion in its causation. Unfortunately, there is a paucity of work that combines consideration of emotional variables with their possible physiological mediators. I will discuss various theories of emotional causation of death with special reference to their possible physiological modes of action.

Sudden death from heart disease claims 300,000 Americans per year (1). The belief that sudden death can be associated with emotional flooding has enjoyed a long popularity in common folklore. In what must be one of the earlier case reports, dating from 50 A.D., St. Luke reports that when Ananias was charged by Peter, "You have not lied to man but to God," Ananias fell down dead (Acts 5:1–2).

Anecdotal evidence has accumulated on sudden death in humans and animals exposed to certain stress situations. The development of this research topic parallels much of the development of general stress studies. Initial interest was expressed by Cannon (2) and Selye (3), after which research bifurcated into psychological and physiological studies.

In 1942 Cannon wrote his now classic paper on voodoo death (2). He searched through the anthropological literature and found a number of reports of otherwise healthy people dying inexplicably after being hexed or violating some taboo. Cannon speculated that people died from suddenly flooding excessive adrenal discharge. As one example, he cites a case originally reported by Merolla in his 1692 diary of a Congo voyage.

> A young Negro on a journey lodged in a friend's house for the night. The friend had prepared for their breakfast a wild hen, a food strictly banned by a rule which must be inviolably observed. . . . The young fellow demanded whether it was indeed a wild hen and when the host answered "no," he ate of it heartily and proceeded on his way. A few years later when the two met again, the old man asked the younger if he would eat a wild hen. He answered that he had been solemnly charged by a wizard not to eat that food. Thereupon the host began to laugh and asked him why he refused it now after having eaten it at his table before. On hearing this news the Negro immediately began to tremble, so greatly was he possessed by fear, and in less than 24 hours he was dead.

Engel (4) collected a number of anecdotal case reports of people dying suddenly in the setting of acute stress.

> A 71 year old woman arrived by ambulance at the Emergency Room, accompanying her 61 year old sister who was pronounced dead on arrival. The patient collapsed at the instant of receiving the news. An EKG showed AV dissociation . . . left bundle branch block and myocardial damage. Shortly she developed ventricular fibrillation and died. (p. 774)

The explanatory models for this occurrence are still being formulated. It is my premise that a variety of factors combine to result in emotional sudden death and that a rigid division between psychological factors and physiological factors is inappropriate. However, I will present, as separately as possible, the psychological and physiological aspects of sudden death.

PSYCHOLOGICAL THEORIES

Overwhelming Stress

Engel (4) collected histories of 170 emotional sudden deaths. Death usually occurred around losses, situations of personal danger, and occasionally some paradoxical situations of great relief, pleasure, or triumph. All these situations had certain stress-related factors in common: 1) being impossible to ignore; 2) evoking intense emotions; and 3) involving a situation in which the person had no control.

Dr. Dimsdale is Instructor in Psychiatry, Department of Psychiatry, Massachusetts General Hospital and Harvard Medical School, Fruit St., Boston, Mass. 02114.

This work was supported in part by National Institutes of Health grant HL-19567 from the National Heart, Lung and Blood Institute. The author wishes to thank Drs. Ned Cassem, Thomas Hackett, J. Alan Herd, and Richard Liberthson.

Hopelessness

Other studies concentrate on the hopelessness of the individual in the situation. Richter (5) described sudden death in rats that was apparently caused by hopelessness. He devised an experimental drowning apparatus in which normal rats could survive for many hours; however, there were always some rats who died within moments. In his next phase of research, he immobilized each rat in a bag while its whiskers and facial hair were shaved off; the rats were then dumped into the tank. Richter reports, "The first rat swam around excitedly on the surface for a very short time, then dove to the bottom where it began to swim around nosing its way along the glass wall. Without coming to the surface a single time, it died two minutes after entering the tank" (p. 194). Richter's initial conclusion was that trimming off the whiskers probably destroyed the rat's most important contact with the outside world. However, further studies revealed that restraint itself was sufficient to cause sudden death; some wild rats died while being held immobilized in the hand. He concluded that the situation of restraint, of being hopelessly trapped, led to a severe fear and rage reaction. The hopelessness of the situation caused the rats to give up. Interestingly, there was no adrenergic effect on heart rate, which slowed rather than accelerated. Richter speculated that the rats died a vagal death, and pretreatment with atropine indeed spared 3 rats of a group of 25 from prompt death.

A number of studies emphasize the hopelessness and helplessness that precedes sudden death. Schmale (6), Saul (7), and Engel (8) refer to this as "giving up-given up response." Bruhn and associates (9) described the "Sisyphus pattern"—the individual strives incessantly and with no chance for satisfaction or success.

Predilection to Death

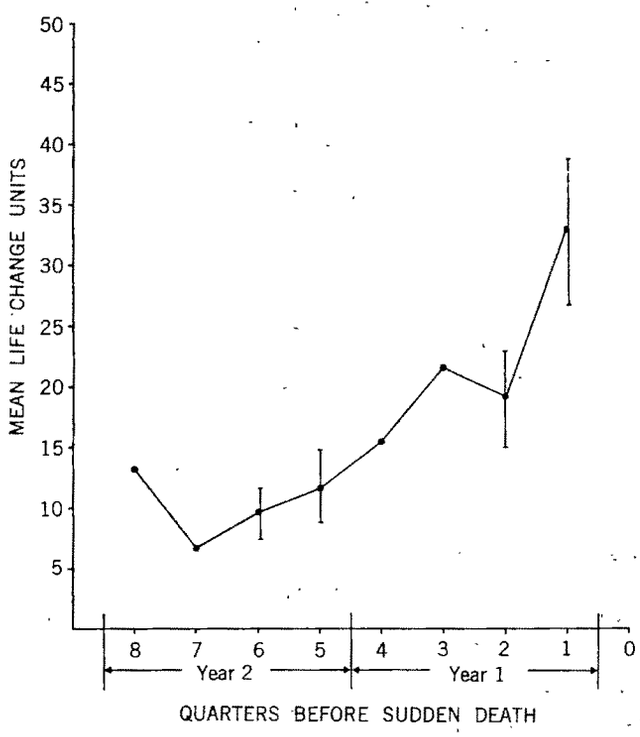
Weisman and Hackett (10) described a predilection to death among surgical patients. They noted a small number of patients who accurately predicted their deaths. These patients regarded their impending deaths without anxiety or depression and were convinced that death was not only inevitable but desirable. The particular cause of sudden death varied from case to case.

> At the age of 41, the patient had undergone an abdominoperineal resection for cancer of the rectum, which kept her an invalid for the next 28 years. . . . The patient's misfortunes multiplied as the years of invalidism went on. Her favorite brother died from a painful rectal carcinoma leaving a large family destitute. . . . In rapid succession three of her sisters died. . . . Finally her loyal husband died . . . [When seen by the psychiatrist she had a striking] Leaden expression of anguish . . . which in its solemn immobility resembled a death mask. . . . She easily stated her conviction that death would occur in a few days and went on to say she had wanted to die for many years. . . . She told of the deaths in her family, of watching through the long dreary years the death of nearly everyone around her. . . . She thought of herself as a plump and sickening slug swallowing and feeding on death. . . . In speaking of her own death, she did not merely intimate that the long sought end was near, but avowed that she would be killed by surgery. After a previous operation she had a pulmonary hemorrhage. . . . Now she was certain another lung hemorrhage would recur except that this time she would certainly die. Eight days after surgery she unexpectedly succumbed to a massive pulmonary hemorrhage. (10, pp. 235–236)

Life Changes

Rahe and associates (11), who have explored the effects of life changes in illness, developed a scale of 42 items (schedule of recent events or SRE) and have investigated the correlation of medical illness with an increased number of these life events. Whereas the previously mentioned studies have looked at the subjective meaning and impact of events, the SRE focuses on the sheer accumulation of events that may be significant or novel to the individual. Rahe and Romo (12) looked at the life event scores of individuals dying suddenly from myocardial infarction and studied the histories of 61 individuals who died suddenly of coronary artery disease and who had previously been in good health. Spouses or next of kin were interviewed concerning the deceased's recent events. In the two years prior to sudden death they found a 143% increase in life events ($p<.005$, figure 1).

All of these psychological theories have assumed that stress is a sine qua non of sudden death—stress of flooding intense emotion that is impossible to ignore, stress of hopelessness and giving up, stress of predilection and longing for death, and stress of accumulating life events. In this sense sudden death is regarded as just another manifestation of the organism's response to stress. What is puzzling is that large numbers of people are under great stress, yet few die suddenly.



PHYSIOLOGICAL THEORIES OF SUDDEN DEATH

The physiology of response to stress is complex. I will focus on stress and the autonomic nervous system. It is clear that the so-called autonomic nervous system is not without higher cortical influence. Since most sudden deaths appear to result from cardiac events, I will review a number of articles that discuss the relationship of emotional stress to autonomic cardiovascular response.

Hypertension

The relationship of stress to hypertension is widely recognized. Among many articles, Graham's (13) is perhaps the most graphic. In 1943 he measured the blood pressure of soldiers resting on the beaches after 2 years of continuous desert warfare in Libya—26% had diastolic blood pressures greater than 100, and most of these returned to normal after a few weeks of rest.

FIGURE 1
Helsinki Study of Life Changes Units and Sudden Death

Cardiac Rhythm

There has been considerable documentation of the relationship of stress to heart rhythm. Gantt (14) has completed a number of studies on the effect of the mere presence of a person on the heart rate of dogs. He describes a famous neurotic dog named V3 who for his 8 years of life manifested a striking response to the approach of a person. His heart rate would drop from 200 beats per minute to 40 beats per minute. On occasion, V3 responded with asystoles up to 8 seconds. Even nonmisanthropic dogs have a marked physiological response to the presence of a person. The routine effect of petting dogs behind the ears is an initial increase in the heart rate and then a drop to 30–40 beats below the baseline rate.

The presence of a person also has a noticeable cardiac effect on other persons. Lynch and associates (15) described the effect of human contact on cardiac arrhythmia in coronary care patients. They noted heart rate changes of over 30 beats per minute, doubling of frequency of abnormal heart beats, and major changes in cardiac conductivity during routine interactions such as pulse taking.

There are a number of studies of heart rate in response to stress. Cardiac arrhythmia can occur in persons without cardiac disease when they are exposed to routine stress or to more extreme stress. Taggert and associates (16) continuously monitored the ECG of normal individuals driving in routine traffic and found ST depression, ectopic beats, and occasional premature ventricular contractions (PVCs). It can be inferred that the stress does not have to be unusually great to elicit cardiac abnormalities. Taggert and associates (17) also looked at the response of healthy subjects to the stress of public speaking. Six out of 23 healthy individuals developed ectopic beats of over 6 per minute while speaking. They found that these abnormalities could be suppressed by giving a beta-adrenergic blocking agent. Moss and Wyner (18) examined medical house officers presenting at grand rounds and found frequent tachycardia up to 180 beats per minute in the minute before giving their talk and the first minute of presentation. Lapiccirella (19) noted transient ST depression on the ECGs of healthy individuals before surgery and on initial imprisonment. Friedman (20) noted similar changes in bank accountants before audits.

Cardiac responses to stress situations may be stable over an extended time. Newton and Gantt (21) demonstrated a persistence in dog heart-rate response to a single-trial conditioning situation by ringing a bell and then administering a single strong electric shock to the dog. The stress of the shock led to a pronounced change in heart rate. When the stimulus of the bell ringing without the electric shock was repeated, the same heart rate changes were observed in some dogs for over a month.

Sigler (22) demonstrated that recall of emotionally upsetting situations was sufficient to produce transient ECG changes in patients with heart disease. One of his patients was a 69-year-old concentration camp survivor. The patient's ECG changed dramatically as he began recounting his experiences in the Nazi concentration camps. Specifically, he developed "changes in the QRS complex in V2 and greater depression of the RT segment and more markedly negative T in V3, V4, and V5, indicating greater ischemia" (22, p. 60).

A number of studies directly demonstrated that heart rate and arrhythmias can be modified by learning. Weiss and associates (23) used instrumental conditioning in 8 patients with chronic PVC. All showed some degree of learning heart rate control, and 5 showed decrease in PVCs in association with their decrease in heart rate. Four patients showed persistence of the lowered PVC frequency for up to 21 months after the conditioning trial.

Lown and associates (24) studied the effects of stress on cardiac rhythm in dogs. Heart rate was paced and a transthoracic shock was applied. The threshold for the amount of shock necessary to trigger a premature ventricular contraction was established under normal conditions. Under the stress condition of total immobilization, the threshold for triggering PVCs was lowered to one-third of its control value.

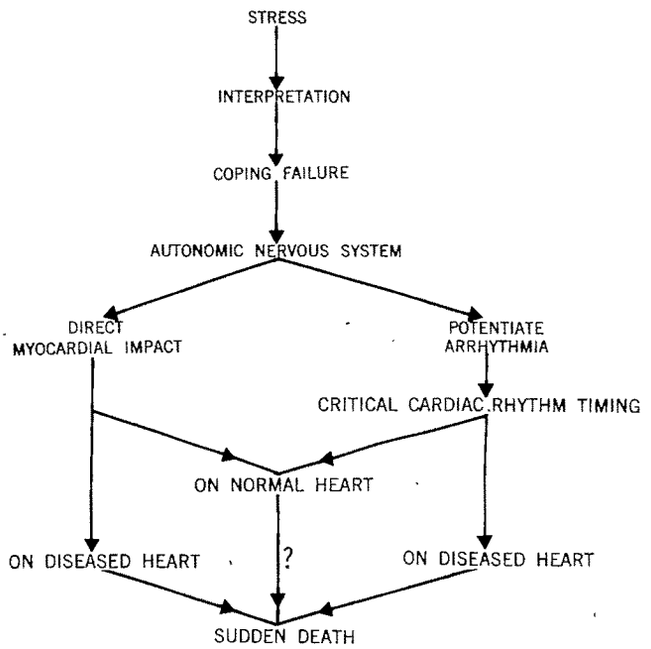
Myocardial Necrosis

The increased interest in animal behavior has brought a number of reports of animals dying suddenly of unknown causes in stress situations such as captivity. Gustafson and Petreman (25) noted spontaneous myocardial necroses in captive golden-mantled squir-

rels. Schmidt (26) looked at hearts of arctic ground squirrels shot wild and those killed after 2 weeks of captivity. The captive squirrels' hearts contained numerous areas of focal necrosis. Raab and associates (27) elicited focal myocardial necrosis in 25% of a series of 12 wild rats subjected to the frightening experience of listening to a taped cat-rat fight.

Selye (3) and Keegan (28) suggest that emotional stress leads to increase in catecholamines and glucocorticoids, which can cause hypoxia and disturbed cardiac conduction. Intravenous administration of large amounts of epinephrine in man can cause myocardial infarct or focal necrosis with subpericardial hemorrhage (3).

Overstimulation of the parasympathetic nervous system can also result in cardiac damage. In monkeys, continued electrical stimulation of the right vagus resulted in myocardial necrosis. Stimulation of the lateral hypothalamic nuclei led to subendocardial hemorrhage and microinfarct (29, 30).



Arteriosclerosis

The presumptive cause of sudden death is arrhythmia. People with coronary artery disease are prone to develop arrhythmia. The prevalence of coronary artery disease is rather startling. Enos and Holmes (31) studied autopsies of Americans killed in the Korean War. The average age at death was 22; 77.3% of these young men showed evidence of arteriosclerosis. Hinkle and associates (32) studied a random group of 300 men aged 55 and recorded their ECG's for 6-hour periods of normal activity: 92% had asymptomatic periods of dysrhythmia and conduction disturbance, 76% had supraventricular premature contractions, 62% had PVCs, and 7% had deficits of cardiac conduction. In a 7-year follow-up study on this group they noted an increased incidence of sudden death in those men who had demonstrated PVCs or deficits of cardiac conduction.

Dive Reflex

Diving animals possess an interesting reflex that may be relevant to mechanisms of sudden death (33). They have a characteristic response to immersion of their face in water—bradycardia, decreased blood flow to skin and viscera, fall in blood pH, and rise in arterial pressure, lactic acid, blood CO_2, and potassium. This response is functional as an oxygen-conserving reflex. The diving reflex is rather inconsistent in man and can be lessened by higher cortical control. It is assumed that the bradycardia in the dive reflex is vagally mediated (34). Many deaths from myocardial infarction appear to be vagal deaths, i.e., the heart slowing to the point of asystole or ventricular fibrillation. Some researchers think that metabolic products from ischemic myocardium may activate the dive reflex as a misguided attempt to conserve oxygen (33). Hinkle and associates' study of 300 middle-aged men noted that 34 men showed a sustained relative bradycardia in daily life activity. After 7 years of follow-up

FIGURE 2
Conceptual Setting for Emotional Causes of Sudden Death

23% of the men with sustained relative bradycardia had died suddenly, whereas the incidence of sudden death in the total population sample was only 8% (35).

There may be subtle interaction between the vagal dive reflex and the adrenal response. Hartley and associates (36) suggest that

> Increased levels of catecholamines may predispose an individual to ventricular arrhythmias. The normal heart at exercise is under catecholamine stimulation. The high heart rate that occurs with exercise protects against ischemia. However, the rapid decline in heart rate after exercise exposes the myocardium to the effect of circulating catecholamines which disappear slowly from the blood.

This model suggests that sudden death occurs in the setting of simultaneous vagal and adrenergic excess stimulation.

DISCUSSION

Neither the psychological nor the physiological explanations of the causes of sudden death are firmly established. That there is a connection seems indubitable. The central question is why so few people die of an emotional sudden death. We must assume that sudden death occurs only when a number of factors are present simultaneously and that, fortunately, the odds of this occurring must be small. Figure 2, a flowchart of possible emotional causes of sudden death, illustrates that stress on a diseased heart at a certain stage in the cardiac cycle may trigger fatal arrhythmias; one must remain agnostic about the possi-

bility of stress-induced fatal arrhythmia in a completely healthy cardiovascular system.

Research Implications

This review has considered sudden death as a unitary phenomenon; thus I have discussed voodoo death, predilection to death, and sudden death. It is quite possible that these deaths do not result from the same mechanism. Future studies must be explicit in defining what constitutes sudden death. There is also confusion about antecedent causes of sudden death; the effects of sudden acute stress and prolonged accumulating stress may very well be different. It is not sufficient to state that the individual was "under stress" without specifying type and duration.

The most striking finding concerning research strategy is the absence of collaboration between cardiologists and psychiatrists. Cardiology journals are replete with studies describing the incidence and possible cardiovascular mechanisms of sudden death. Any attention given to emotional state is usually reserved for a brief diffuse sentence in the conclusion. The psychiatric journals contain case reports and an occasional attempt to summarize common emotional factors in sudden death, with little regard for the patient's prior cardiovascular status. Collaboration on psychosomatics of coronary disease is well underway with reference to personality types prone to myocardial infarction (37) and factors in rehabilitation of these patients (38). Unfortunately, this model of collaboration does not extend to consideration of sudden death per se.

This lack of collaboration results partly from the difficulties involved in studying sudden death. Sudden death is rare enough to make a prospective study in an unselected population unwieldy for both cardiologist and psychiatrist. However, collaboration should be possible in a selected population. Several approaches are possible: 1) patients in coronary care units, clearly at risk for fatal arrhythmias, could receive careful psychiatric evaluation; 2) activity of the peripheral sympathetic nervous system could be monitored by urinary assay; and 3) the methodology of Lynch and associates (15) could be adopted, i.e., a diary kept of daily occurrences matched with continuous rhythm strips. The last possibility would enable the clinician to study the occurrence of fatal arrhythmia with reference to preceding events—emotional, cardiac rhythm, and adrenergic discharge—and then interview the resuscitated patient. Until this sort of methodology is applied, we are likely to persist in work that is interesting but not sufficiently understood.

Clinical Implications

Because psychiatrists do not understand the exact composition of lethal emotional stress, we must routinely intervene in cases of patients at risk. Nowhere is this more pressing than in the coronary care unit, where emotional arousal, particularly anxiety, is not only distressing but potentially lethal and deserves treatment just as hypokalemia does. The treatment alternatives are eminently accessible, ranging from the supportive presence of the physician and antianxiety agents to more specialized techniques of psychotherapy and behavioral therapy.

COMMENT

This paper is not an exhaustive review of the emotional causes of sudden death. Instead it reviews concepts and key studies pertinent to an understanding of the phenomenon. The goal of this review is to stimulate interest in this very important and surprisingly neglected area. In both research and clinical practice, collaboration between psychiatry and medicine is sorely needed in the area of emotional causes of sudden death.

A Survey of Tardive Dyskinesia in Psychiatric Outpatients

BY GREGORY M. ASNIS, M.D., MICHAEL A. LEOPOLD, M.D., ROGER C. DUVOISIN, M.D., AND ARTHUR H. SCHWARTZ, M.D.

The authors found a high prevalence—43.4%—of tardive dyskinesia in a sample of psychiatric outpatients, a population previously thought to be at nominal risk for development of this syndrome. There was no significant relationship between the presence of dyskinesia and age, sex, years of neuroleptic use, or various organic factors. The effects of dentures and of drug combinations are discussed, and it is noted that structured scales of dyskinesia and videotape recordings are important tools in diagnosing and following the course of dyskinesia.

TARDIVE DYSKINESIA, a neuroleptic-induced neurological syndrome, is characterized by involuntary movements of the tongue, face, jaws, and lips; occasionally, there are choreoathetoid movements of the extremities or trunk (1). Since the syndrome was first reported in 1956, various surveys have found its prevalence to be as high as 56%. These surveys focused exclusively on psychiatric inpatients, particularly chronic patients in geriatric, state, and veterans institutions (2, 3). The surveys have not included psychiatric outpatients, who are often younger, do not suffer the effects of chronic institutionalization, and have had shorter durations of treatment with antipsychotics.

Since tardive dyskinesia is often irreversible, it is essential that the treating physician be aware of its prevalence and of the factors that predispose to or in any way influence its occurrence. At present, the outpatient clinician does not have the necessary information to weigh this risk in treatment with antipsychotic medication. In recent years there have been reports of tardive dyskinesia in a few cases of younger patients who had been on neuroleptic medication for only brief periods of time (1). In this study, we surveyed a psychiatric outpatient population for tardive dyskinesia.

Dr. Asnis is Lecturer, Department of Psychiatry, Mount Sinai School of Medicine, New York, N.Y., where Dr. Leopold was Fellow when this work was done, Dr. Duvoisin is Professor, and Dr. Schwartz is Associate Professor. Dr. Leopold is now Associate Director of Inpatient Services, Princeton University Medical Center. Dr. Asnis is also Research Assistant Professor, Department of Psychiatry and Behavioral Science, State University of New York at Stony Brook, and Staff Psychiatrist, Long Island Research Institute, Central Islip, N.Y. 11722.

Presented in a new research session at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977.

This work was supported in part by National Institutes of Health grant NS-11631 from the National Institute of Neurological and Communicative Diseases and Stroke to Dr. Duvoisin.

The authors would like to acknowledge the statistical help of Dr. Harry Smith, Chairman, Department of Biostatistics, Mount Sinai School of Medicine, and the advice of Dr. Marvin Stein, Professor and Chairman, Department of Psychiatry, Mount Sinai School of Medicine.

METHOD

Sixty-nine patients were randomly selected from the group of 250 patients receiving antipsychotic medication in the psychiatric outpatient clinic of Mount Sinai Hospital at the time of the study. Patients were included in the study, regardless of diagnosis, if they had been taking antipsychotic medication for at least 3 months and if they were not taking medication at the time of evaluation, but their last dose was within the 3 preceding months.

After giving informed consent, all patients were interviewed and examined by one of the investigators (G.M.A. or M.A.L.). The presence of dyskinetic movements and their location and severity were rated on the Abnormal Involuntary Movement Scale (AIMS), a 5-point scale that has been found to assess tardive dyskinesia reliably (4, 5). Videotapes were made of all patients who appeared to have involuntary movements and of 8 patients who seemed to have no such involuntary movements and who served as controls for the final evaluations. Three members of the research team (G.M.A., M.A.L., and R.C.D.), including an experienced neurologist who served as a consultant in developing the AIMS (R.C.D.), then made independent ratings of all videotapes by using the AIMS. For the purpose of the survey, patients were considered positive for dyskinesia only if all three raters concurred.

All patients were also evaluated for organicity by means of the Mental Status Questionnaire (MSQ) and the Face-Hand Test (FH) (6). The MSQ consists of 10 orientation and information questions and was rated positive if more than 2 incorrect responses were made. The FH test assesses the patient's ability to perceive double simultaneous stimulation; errors have been reliably associated with brain damage in adults. Patients were rated positive if they made 1 error or more.

Other factors evaluated for possible association with involuntary movements were the duration and type of medication, number and length of hospitalizations, history of amphetamine or alcohol abuse, history of

ECT, personal or family history of neurological disorders, and history of drug-induced extrapyramidal side effects.

RESULTS

Of 69 patients sampled (53 women and 16 men), the three raters concurred that 30 patients (25 women and 5 men) were positive for dyskinesia on the AIMS. This represents 43.4% of our randomly selected outpatient sample. Although there was total agreement among raters on the presence or absence of dyskinesia, some variability existed in the severity of global ratings in 11 dyskinetic patients, with a grade of 1 being the largest difference between any two raters. Of the dyskinetic group, 60% were rated as minimally impaired, 30% as mildly impaired, and 10% as moderately impaired.

Demographic Characteristics

As can be seen in table 1, tardive dyskinesia was present in 47.2% of the women and 31.2% of the men surveyed, a difference that did not reach statistical significance (p=.40).

The mean age of the survey population was 45.5 years; the dyskinetic group had a mean age of 45.8 years and the nondyskinetic group of 45.3 years (p=n.s.). The percentage of patients diagnosed as dyskinetic was the same for those 50 years old or younger and those 51 or older (43.4%).

The mean age of the men with dyskinesia (37.8 years) was similar to that of those without dyskinesia (39 years). Mean ages for the two groups of women were also similar (47.4 years for the dyskinetic group and 47.8 for the nondyskinetic group). The sample is broken down by age and diagnosis of dyskinesia in table 1. The youngest patients with dyskinesia were 3 women aged 20, 22, and 28 years, and 1 man aged 20.

Medication and Organic Factors

The mean number of years on neuroleptics was slightly less in the dyskinetic group than in the nondyskinetic group (4.59 years versus 5.50 years, p=n.s.). It can be noted in table 2 that 46.7% of the patients with dyskinesia had been on neuroleptics for 2 years or less. Four patients (13.3%) with dyskinesia had received neuroleptics for 1 year or less, with the shortest duration being 8 months. All of the men with dyskinesia had been on neuroleptics for 5 years or less, the majority (4 of 5) for 2 years or less. Of the 30 dyskinetic patients, 2 had terminated neuroleptics 1 week prior to the evaluation. Both patients were immediately restarted on their medications, and 2 months later they were again found to be dyskinetic.

Despite careful assessment of hospital charts and interviews with patients, we were unable to assess with confidence all of the past neuroleptics and dosages patients had been given since their treatment began. Therefore, we could not assess which types of medications and dosage levels may be more often associated with tardive dyskinesia. The butyrophenones, phenothiazines, and thioxanthenes were all noted in the medication histories of patients with dyskinesia in this survey.

Neurological histories and history of ECT, alcoholism, amphetamine abuse, and cerebral dysfunction as reflected by the MSQ or FH test were approximately the same in the two groups (see table 3). Chart review revealed no active medical or neurological problems, no endocrinopathies, and no abnormal blood chemistries. Family history of movement disorders was found in 1 dyskinetic patient (Parkinson's disease) and

2 nondyskinetic patients (Parkinson's disease and familial tremor). No evidence of Huntington's chorea was present in patients or family members.

By chart review and interviews with patients, we verified past drug-induced dystonia in only 3 dyskinetic patients (10%) and 1 nondyskinetic patient (2.6%).

Miscellaneous Factors

The degree of psychopathology was assessed indirectly by the total number of psychiatric hospitalizations. The two groups had approximately the same mean number of hospitalizations (1.6 and 1.5). Medians were 2 and 1 for the dyskinetic and nondyskinetic groups, respectively. Statistical analysis indicates a trend toward more than 1 hospitalization among the dyskinetic group ($\chi^2=3.76$, $p<3.06$). Because patients' memories and charts were often vague about the duration of each hospitalization, exact times were not calculated, but all were for less than 1 year.

One factor that was frequently associated with dyskinesia was the presence of dentures—50% of patients with dyskinesia (N=15) had dentures compared with 18% (N=7) in the nondyskinetic group ($\chi^2=6.61$, $p=.01$). Of the 15 dyskinetic patients with dentures, 6 had vermicular movements of the tongue and 2 had choreoathetoid movements of the extremities. Only 6 of the dyskinetic patients with dentures had abnormal movements that were limited to their jaws.

An interesting finding was that in the total group of 69 patients surveyed, 9 patients were on neuroleptics alone and 5 of these (55.6%) had tardive dyskinesia. Of 22 patients on neuroleptics in combination with antiparkinsonians alone, 6 patients (27.3%) had tardive dyskinesia. Although a trend was noted, it was not statistically significant ($\chi^2=1.17$, $p=.28$).

DISCUSSION

Past surveys have reported the prevalence of tardive dyskinesia to range from 0.5% to 56%, with most recent studies citing the highest percentages (2, 3). These studies, which focused on chronically institutionalized populations, have given rise to the clinical impression that patients particularly at risk to develop dyskinesia 1) are female, 2) have organicity or prior brain damage (factors 1 and 2 are controversial), 3) are older (over 55 years old), and 4) have used neuroleptic medication for more than 2 years (1, 7, 8).

Before our outpatient survey of tardive dyskinesia, it was commonly felt that dyskinesia was infrequent in psychiatric outpatients being treated with neuroleptics and was mainly a problem of chronically institutionalized patients (1). The most striking result of our survey was the high prevalence (43.4%) of tardive dyskinesia in a population previously described as being at nominal risk for tardive dyskinesia. The dyskinetic group was young (average age of 45.5 years), had a short duration of neuroleptic medication (less than 2 years for 46.7%), and were not chronically hospitalized (median of 2 hospitalizations). There was no significant relationship between the presence of dyskinesia and age, sex, years of neuroleptic use, organicity, history of ECT, amphetamine or alcohol abuse, or of neurological disorders in the patients or their families. Perhaps the predisposing factors reported in previous studies were characteristic of their sample populations—chronically institutionalized patients.

Two associated findings of questionable significance were those related to dentures and antiparkinsonian medication. Dentures were worn by 50% of the dyskinetic group but only 18% of the nondyskinetic group, but only 6 dyskinetic patients who wore dentures had movements limited to the jaw, and none complained of discomfort. Since there were no denture problems and most of these patients had movements of the tongue and/or extremities, we believe that the movements were not induced by dentures.

Recently there have been reports that antiparkinsonians lower the threshold for amine stereotyped behavior in animals and when used in conjunction with neuroleptics may increase the risk of tardive dyskinesia in man (9). Our results suggested a contrary trend: 27.3% of patients on neuroleptics and antiparkinsonians had dyskinesia, whereas 55.6% of those on neuroleptic medication alone were dyskinetic. However, since our survey was not designed to evaluate the effects of antiparkinsonians specifically, it is difficult to draw conclusions from these data.

It appears that there is little to guide the clinician in predicting which outpatients may develop dyskinesia. We would agree with the present literature that the best way to reduce the occurrence is to give neuroleptic medication only to schizophrenic patients, using non-neuroleptics to treat other states, such as anxiety and depression. Since dyskinesia is often irreversible, it is incumbent on the physician to detect the syndrome early in its course so medication can be discontinued if the mental condition permits. Frequent examinations of the patient, assessing early oral-facial movements, particularly vermicular movements of the tongue, and temporary withdrawal of antipsychotic medication to evaluate an early dyskinesia that may have been masked have been suggested (10). We believe that early detection of dyskinesia is facilitated by using a structured dyskinesia scale like the AIMS and scales developed by Simpson and associates (11) and Crane and Naranjo (12), which can bring out subtle dyskinetic movements. This should be done before initiating treatment and at fixed intervals thereafter.

In the present study, the videotape recording of the dyskinesia examinations was invaluable in increasing diagnostic sensitivity, particularly of early signs of tardive dyskinesia. The videotapes included not only the examination itself but also a 1–2-minute interval of the patient sitting alone in the room. One patient did not show dyskinetic movements during the structured evaluation, but clearly had such movements during the period when he sat alone.

The videotape also allowed several observers to rate

the same examination at a later date. This is important since movement disorders can vary from one examination to the next in quantity and quality. The recordings can also be used to follow the development of these movements and to determine how they first appear or change over time. Most studies of tardive dyskinesia have not used videotape or movie recordings of the dyskinesia evaluations. Such recordings seem to be essential to future research on the clinical manifestations and progression of tardive dyskinesia.

CONCLUSIONS

This study demonstrates that outpatients as well as inpatients receiving neuroleptics are at a substantial risk for tardive dyskinesia. When neuroleptics are essential to the treatment of the patient, early detection of involuntary movements becomes critical. The present study suggests that the sensitivity of diagnosing tardive dyskinesia can be increased by examining the patient with a structured dyskinesia rating scale and videotaping the examination for evaluation by other physicians. Early, subtle signs can be detected more easily by following the patient's progress with subsequent videotaped evaluations. Further study is necessary to better understand the effects of medication combinations and other factors on the occurrence and development of tardive dyskinesia.

An Evaluation of a Unique New Antipsychotic Agent, Sulpiride: Effects on Serum Prolactin and Growth Hormone Levels

BY DAVID H. MIELKE, M.D., DONALD M. GALLANT, M.D., AND CRAIG KESSLER, M.D.

Sulpiride is a new and chemically different neuroleptic. In a study of 16 severely ill schizophrenic patients, this compound displayed definite evidence of antipsychotic activity while producing few adverse reactions. The relative absence of extrapyramidal side effects may indicate that sulpiride has a low potential for producing tardive dyskinesia. Two patients who did not develop significant increases in prolactin levels did show a definite therapeutic response to sulpiride. Thus it appears that central dopaminergic blockade in the hypothalamic area is not a prerequisite for antipsychotic activity.

SULPIRIDE (±) is a new drug chemically unrelated to known neuroleptic agents. It is a member of a class known as orthopramides or *o*-anisamides and has the chemical name of N-[(1-ethyl-2-pyrrolidinyl)-methyl]-2-methoxy-5-sulfamoylbenzamide (1). The structural formula is shown in figure 1.

In animal studies sulpiride has displayed strong antidopamine effects (1), but its influence on norepinephrine is unknown (a review of the laboratory profile is available elsewhere) (2, 3). Acute and chronic administration of sulpiride to animals has resulted in toxicity and catatonia only at very high doses. Lower species excrete greater numbers of metabolites than do higher species.

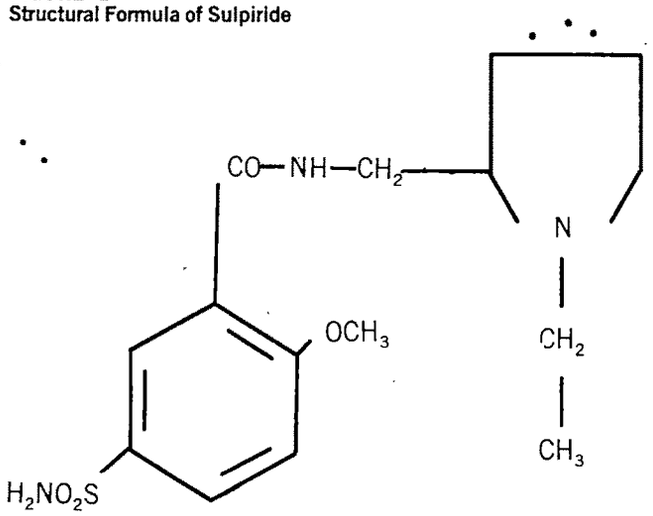
Studies of human volunteers have shown that sulpiride is rapidly absorbed with oral and parenteral administration and that its half-life is relatively short (only about 8 hours) (1). Virtually complete elimination of a single dose occurs at 24 hours. Using ^{14}C labeled sulpiride administered orally, researchers found that approximately 40% of the drug was absorbed, and it was excreted renally in an unchanged form (1). To our knowledge, no metabolites have been found in man.

The clinical application of sulpiride began in the field of gastroenterology in 1966, and it currently is used as an anti-ulcer medication in other countries. Subsequently, sulpiride was used in the treatment of various psychopathological disorders, including psychotic states (3–7) and neurotic depression (3, 4, 8). The vast majority of studies suggest a broad therapeutic spectrum of activity and a low incidence of side effects. Jouglard and associates (9) found that toxicity is minimal, as evidenced by lack of mortality after single-dose ingestions of up to 7 g. These authors reported that some patients exhibited extrapyramidal phenomena for up to 48 hours.

In a previous evaluation of sulpiride in 10 schizophrenic patients, the Tulane research team found it to be an effective agent, free of side effects at moderate doses (2). Further trials were indicated to study the efficacy and adverse reactions at higher doses and to study the effects on prolactin and growth hormone over time.

METHOD

The study was conducted using 16 chronically hospitalized, severely ill schizophrenic patients under close supervision on a special research unit. The 6 men and 10 women were free of any significant disabilities of the cardiovascular, endocrine, hematopoietic, renal, and hepatic systems. None of the subjects had a history of alcoholism, cerebral trauma, leukotomy, epilepsy, recent ECT, or neurological disease. Informed consent was obtained from the patient and the closest living relative after the nature of the procedure had been fully explained.



The average age was 38.6 years, and the duration of hospitalization averaged 15.5 years. After a 14-day drug-free period, sulpiride was administered twice daily for 12 weeks using a flexible schedule of increases dependent on therapeutic response and the appearance of adverse reactions. (Sulpiride was supplied by Warren-Teed Pharmaceuticals, Horsham, Pa.) The starting dose was 400 mg daily, with a planned maximum of 2600 mg per day. A small comparison group of 6 patients was administered standard neuroleptics in optimal dosages using the same schedule as that used with the sulpiride subjects. Prolactin and growth hormone blood levels were determined by radioimmunoassay procedures.

Clinical tests were performed as follows: supine and

FIGURE 1
Structural Formula of Sulpiride

standing blood pressures three times weekly; ECG at baseline and weekly; and photosensitivity skin tests and complete eye examination, including slit-lamp examination, at baseline and termination of the study. Complete blood count, urinalysis, and SMA-12 were conducted at baseline and subsequently every other week. Serum prolactin and growth hormone levels were ascertained at 11 a.m. at baseline, on days 1, 10, 17, 24, 52, and 80 (4 hours after the morning dose); and 3 days after termination of active drug treatment. Psychometric measures included weekly global ratings (−1 to +3) based on a brief mental status examination. In addition, the Brief Psychiatric Rating Scale (BPRS), Clinical Global Impressions (CGI), and the Nurses' Observation Scale for Inpatient Evaluation (NOSIE) were rated at baseline, weeks 4 and 8, and termination. Adverse reactions were evaluated on a daily basis.

All data were analyzed by the George Washington University Biometric Laboratory, ECDEU section, using analysis of variance—repeated measures model.

RESULTS

Consistent with our first evaluation of sulpiride, the overall findings showed that this agent exerts a definite neuroleptic effect at doses above 400 mg daily. In the severely ill schizophrenic patients, some beneficial changes first appeared at doses above 2000 mg daily. Maximum daily doses administered were 1600 mg (4 subjects), 2400 mg (2 subjects), and 2600 mg (10 subjects).

The CGI, BPRS, and NOSIE strongly supported the clinical findings of improvement. Significant change scores ($p<.05$) across time were noted on all scales and each factor for which improvement was possible (core schizophrenic symptoms).

The study also indicated that sulpiride elevated serum prolactin levels and depressed growth hormone levels over time. It should be noted that the age difference between the sulpiride patients (see table 1) and the comparison group (see table 2) was significantly different ($p<.001$). Low doses of the neuroleptic rapidly elevated serum prolactin levels, but increasing the doses generally did not produce higher hormone concentrations. Serum prolactin values rapidly diminished after drug withdrawal.

In our first evaluation of sulpiride (2), serum prolactin levels were determined by a different laboratory using the same radioimmunoassay technique and were generally lower than those levels found in table 1. No correlation was found between increased prolactin levels and individual improvement in global ratings. Two subjects improved, but their serum prolactin levels did not show a significant increase above baseline levels.

ADVERSE REACTIONS

During this 12-week study only 1 of the 16 sulpiride patients (patient 2) exhibited side effects (a dystonic reaction on 2 separate occasions) when receiving doses of 1800 mg or greater. On each occasion he responded to a single dose of anticholinergic medication. No signs of sedation or antiadrenergic effects were observed in this group of patients. Laboratory values were not significantly abnormal, although the white blood cell count increased moderately in 8 patients without a shift in differential count.

For 7 subjects who were receiving doses exceeding 2200 mg per day, the ECG showed no changes from baseline configurations. For the remaining 9 patients, the only ECG change was a broadening and flattening of T-waves at various dosages over 1600 mg per day. As observed in our original sulpiride study, the only ECG alterations produced by sulpiride were those benign, nonspecific changes usually occurring at levels above 2200 mg daily.

Slit-lamp evaluation did not reveal any ophthalmological changes during treatment with sulpiride. There was no evidence of photosensitivity. No other significant clinical or laboratory abnormalities were noted.

DISCUSSION AND SUMMARY

The regulation of peptide hormones has been the subject of much investigation. Based on direct and indirect evidence, the modulation of prolactin is mediated by a prolactin membrane receptor (10), by the obligatory role of monoamines (11–14) in the hypothalamus and the pituitary (15, 16), and by the presence of a prolactin-inhibiting factor that has not yet been isolated (17). This prolactin-inhibiting factor may be dopamine itself, since high concentrations in the hypothalamus will inhibit the release of prolactin (15–17). There is evidence that both norepinephrine and dopamine modulate growth hormone release (14, 18).

Several commonly used drugs alter serum prolactin and growth hormone levels. Centrally acting com-

*GH and prolactin are measured in nanograms per milliliter.

pounds known to antagonize dopaminergic neurons, to stimulate serotonergic neurons, or to release thyroid-releasing hormone can profoundly increase serum prolactin levels. Such pharmacological agents include neuroleptics of all classes, tricyclic antidepressants, reserpine, and methyldopa (19–21). Dopamine agonists (e.g., L-dopa, apomorphine, ergot alkaloids) markedly inhibit prolactin secretion (19). It has been observed that antipsychotic drugs lower blood levels of growth hormone (22). However, it is not known whether a drug exerts the same degree of blockade in all dopaminergic pathways.

The consequences of drug-induced shifts in circulating hormones are unknown. Recently, there has been a controversy (23) over the possible increased risk of breast cancer in women exposed to rauwolfia derivatives (24–26). The relationship between chemicals and hormones and the development of tumors is complex. To date, there has been a failure to show an association between carcinogenesis and the use of non-rauwolfia drugs known to enhance prolactin release (24, 25). To our knowledge, neuroleptic-induced depression of serum growth hormone has not been shown to be harmful to adults or children.

In summary, sulpiride is a potentially valuable neuroleptic because of its very low potential for side effects and a wide margin of safety between therapeutic doses and toxic levels. It has been speculated that antipsychotic agents which produce few or no extrapyramidal symptoms have a diminished capability of producing tardive dyskinesia.

Sulpiride tends to elevate prolactin and depress growth hormone values. Increased serum levels of prolactin could not be correlated with individual clinical improvement. It is interesting to note that 2 patients who did not develop significant increases in prolactin levels (a reliable indicator of dopaminergic blockade) did show a definite therapeutic response to an antipsychotic agent. Thus it appears that dopaminergic blockade in the hypothalamic tuberoinfundibular area does not necessarily correlate with therapeutic responses to neuroleptic agents.

Denying the Incredible: Unexplained Deaths in a Veterans Administration Hospital

BY PHILLIP KROLL, M.D., KENNETH SILK, M.D., KENNETH CHAMBERLAIN, M.D., AND ROSALIE GING, M.D.

During July and August 1975 a large number of patients at the Ann Arbor Veterans Administration Hospital experienced unexplained respiratory arrests, and there were six deaths. These were later shown to be due to the deliberate injection of pancuronium bromide, a muscle relaxant. A questionnaire survey of the reactions of the hospital patients and staff to the deaths revealed that the patients had more confidence in the hospital and their medical treatment than did the staff, and those patients who were theoretically most vulnerable used denial to cope with the unprecedented and frightening situation.

THE ANN ARBOR Veterans Administration (VA) Hospital is one of the most active teaching hospitals in the VA system. The full-time attending staff is integrated with the University of Michigan Medical School, and all staff members hold academic appointments. The hospital trains residents, interns, medical students, nurses, and other professionals from the university. During the months of July and August 1975, an increasing number of patients began to experience respiratory arrests. Some of the arrests were among the chronically debilitated or terminally ill, but others caused more concern because they occurred among patients who apparently were stable or experiencing otherwise uneventful recoveries. Although the patients were found apneic and unresponsive, most often in the intensive care unit (ICU), seemingly superlative work by the evening staff managed to revive the majority. However, some patients did die, including a small number whom no one expected to have respiratory complications.

The hospital's medical and surgical staff soon became filled with a sense of unease. By the end of July the chief of anesthesiology had initiated a vigorous chart review to try to determine the cause of the breathing failures. However, the rash of respiratory arrests continued. Multiple hospital emergency calls would often be heard during the day and early evening. Some patients on the medical wards and the ICU began to experience second and even third episodes of respiratory failure. The intensive review of records failed to reveal any consistent medical or pharmaceutical error. The unthinkable slowly became tenable. Might someone be deliberately causing the respiratory arrests?

From July 1 to August 15, 1975, there were 51 respiratory arrests among 35 patients, 6 of whom died under suspicious circumstances (1). Before the outbreak there had been an average of 6 such arrests a month. The situation reached a crescendo on August 15 in the ICU. From 4:30 to 4:50 in the afternoon, first 1 patient, then another, and then a third suddenly stopped breathing. Teams of doctors, nurses, and orderlies successively raced from 1 patient to another, intubating them and placing them on respirators. The chief of anesthesiology was present and noticed the flaccid nature of the patients' muscles. A nerve stimulator was brought from the operating room and applied to one of the patient's arms. It showed evidence of a curarelike muscle blockade. Neostigmine was injected intravenously and there was a dramatic reversal of the patient's muscle and respiratory paralysis. Samples were then taken of serum, bile, and urine for further testing. The unthinkable—that someone was deliberately poisoning these patients—became the most plausible explanation. The Federal Bureau of Investigation (FBI) was called into the case a few hours later.

The nature of the depolarizing blockade made Pavulon (pancuronium bromide) the drug most immediately suspect. Pancuronium is an intravenously injected muscle relaxant that, ironically, is sometimes used in the ICU as an aid in placing conscious patients on mechanical respirators. On September 3, 1975, pancuronium or its metabolites were found in the bile and urine of 2 of the patients who had undergone arrests in the ICU.

The events in the hospital had been chronicled daily in the local press and on the radio and television almost from the moment the FBI had been notified. Speculations in the media were only later followed by

confirmations. Front-page headlines such as "Killer at Large in Veterans Hospital?" were already appearing by August 20, 1975 (2). Both patients and their families expressed concern. The hospital was immediately closed to nonemergent admissions. Steps were taken to increase security. All patients receiving intravenous fluids were placed on 2 wards and closely monitored. Nurses could handle the intravenous apparatus only in pairs. The nursing staff was increased, identification cards were issued to employees, and strict controls were placed on the storage and use of pancuronium. The FBI took over a ward on one of the floors of the hospital, and it soon became common to see both FBI agents and television reporters in the hospital corridors. After being closed to nonemergent admissions for a month, the hospital slowly began to admit a reduced number of patients.

The department of psychiatry, which operates wards on 2 upper levels of the 9-story building, was somewhat removed from the turmoil on the medical and surgical services. The initial revelations were greeted by some in the department with frank disbelief, which only dissipated with the discovery of pancuronium in the body fluids of the ICU patients. The patients on the closed psychiatric unit had quickly begun joking about "Pavulon Pete," but they seemed to feel more secure behind the locked door. They suddenly began to view it as keeping someone else out rather than confining them. It became a matter of great interest as to how the patients and staff in the entire hospital reacted to the possible presence of a killer and the sudden, frightening notoriety of the hospital.

We decided that an anonymous, self-report questionnaire might well be the most unobtrusive manner of obtaining information on the current attitudes of a large cross-section of patients and staff. Those most directly affected by the events had undergone extensive FBI interrogations and were involved in a sensitive criminal investigation; further lengthy psychiatric interviewing at that time was not considered appropriate. The uniqueness of the event almost precluded the formulation of hypotheses about what, if any, pattern of responses might be found. Whatever pattern might develop would have to emerge empirically and inductively from a gathering of information.

METHOD

We developed a questionnaire that attempted to identify patient and staff attitudes and perceptions of the large number of respiratory arrests at the hospital. It consisted of 30 items divided among the following 5 categories: demographic data, the area in which the people were hospitalized or worked, attitudes toward the hospital, opinions of the origin or cause of the respiratory arrests, and attitudes toward the news media coverage.

During the period October 3–6, 1975, questionnaires similar in form and content were given to both patients and staff, to be anonymously completed and returned. Since admissions to the hospital had been severely limited, there were then only 195 patients, compared with an average daily census of 285. There also was a high percentage of extremely ill patients in the hospital, since the healthier patients had been quickly discharged after recovery. Questionnaires were given to 112 patients who were physically and mentally capable of responding; 90 were returned for a response rate of 80%. Seventy-three percent of the patients responding had been admitted after August 15, 1975. These patients may well have represented a self-selected sample of people who were strongly committed to the VA system and tended to minimize difficulties in their care. However, they were randomly distributed among all of the patient categories that were eventually compared. There were 632 employees available for sampling; 315 completed the questionnaire for a response rate of 50%. The occupational distribution of the responding employees was representative of the major job classifications in the hospital. The sample of patients and staff was divided by various criteria in such a way that 2 or more subgroups were formed. These were then compared using chi-square analysis (3).

RESULTS

Comparison of the Patient and Staff Groups

The patients appeared to have a great deal more faith in the hospital during the period of turmoil than did the staff. Only 26% of the patients, compared with 48% of the staff, would have requested the transfer of a relative to another facility. Ninety-three percent of the patients, but only 67% of the staff, stated that they would be willing to be a patient at the hospital in the future. Although 67% of the patients were reassured by the presence of the FBI, only 49% of the staff expressed similar confidence in the agency. These differences were all significant ($p<.005$ level). Seven percent of the patients and 9% of the staff felt that the hospital's reputation had been permanently damaged.

The patients' strong expression of confidence in the hospital came as a surprise. It could not be attributed to lack of information, since media coverage both in the local newspapers and on television was extensive, dramatic, and stressed the possible presence of a killer. We initially believed that much of this faith was realistically based on the hospital's 25-year history of professional service and that many of the patients, faced with limited financial resources, could not realistically contemplate transfer to private care. We also felt this confidence was the product of a sample that was skewed by psychiatric inpatients who were emotionally and physically remote from the events on the medical and surgical services. Far from being in a near panic, most patients seemed to deal with the crisis with relative equanimity. Even at the nadir of FBI fortunes, in the midst of the Hoffa disappearance and the failure to capture Patty Hearst, the patients retained their con-

fidence in the FBI while a more cynical or realistic staff remained skeptical.

However, the suspicion that denial mechanisms were partly responsible for the patients' more sanguine view of the hospital became apparent when the results of questions pertaining to the origin of the dramatic events were obtained. Of the patients responding to the question, only a bare majority (53%) felt that the cause of the events was a deliberate act of murder. Almost an equal number of patients were ready to attribute the origins to more benign, less threatening causes such as patient illness, pharmaceutical mistakes, or medical error. The staff members differed significantly from the patients in their assessment of the events; 70% of those answering the question felt that the respiratory arrests had been deliberately caused ($p<.025$). Of those who believed there was a murderer present, 75% of the patients and 82% of the staff thought that he or she was a hospital worker and not an outsider. Although they were reluctant to be specific, both patients and staff felt the killer had to be medically knowledgeable. The hospital staff was most suspicious of the medical outsider in their own midst—the medical student; the patients were concerned with the person who directly delivered the intravenous injections—the nurse. However, only a few people voiced these suspicions, and they could not be analyzed statistically.

The patients had a greater belief in the ultimate just resolution of events. Eighty-one percent of the patients, compared with only 47% of the staff, felt that whoever was responsible for the respiratory arrests would be apprehended ($p<.005$).

While the patients were about evenly divided as to whether the intensive media coverage was beneficial, the staff was extremely critical. Almost 80% felt that the coverage was exaggerated and not in the best interests of the patients or the public ($p<.005$). The investigators felt that the adverse reactions of the staff reflected employee defensiveness over the negative publicity given the hospital by the news media. Although they were sometimes sensationalized, the facts reported by the media were essentially accurate, but both the patients and staff often used the sensational tenor of the reporting to reject the idea that such coverage served the best interests of the public.

Comparison of Patients and Medical Staff in Relation to Their Proximity to the Events

It became apparent that comparing the total patient group with the total staff group elicited only the grossest of trends. It was difficult to imagine that the psychiatric inpatient could be as concerned about the respiratory arrests and deaths as the medical patient was, or that the radiologist could have the same sense of immediacy of crisis as a nurse or intern on the medical ward. We hoped that by reanalyzing the data in relationship to the subjects' proximity to hospital areas and medical procedures associated with the respiratory arrests, a more meaningful interpretation of attitudes could be made. The lack of concern on the part of the patients noted initially might not be denial but the responses of a large number of emotionally uninvolved patients and simply a form of emotional ignorance; they just did not understand the situation.

We therefore hypothesized that those patients and staff closest to the areas of difficulty would show less faith in the hospital, be more aware of the possibility of murder, and be more approving of the disclosures of the media than those patients and staff relatively distant from the events. It was further proposed that rumor and media coverage had effectively cancelled out any discrepancies in knowledge between patients and staff and that the nearby patients whose very lives were in danger would be even more concerned then their attending physicians. The hospital administration had been quite tight-lipped about the crisis and subsequent criminal investigation, and even the medical staff relied on local newspapers as the principal source of information about the deaths.

The patients were divided into 2 groups—close and distant. Patients were assigned to the close group if they gave a positive answer to any of the 6 questions concerning the medical care or procedures that they had experienced while in the hospital, e.g., receiving general anesthesia, undergoing surgery, receiving intravenous fluids, being hospitalized in the ICU or the coronary care unit, being close physically or emotionally to someone who had experienced a respiratory arrest, or personally having undergone an arrest. All other patients were placed in the distant group. There were 40 patients in the close and 45 patients in the distant group. The staff group was trimmed to just those who performed medical duties, i.e., doctors, nurses, and aides. Staff members were assigned to the close group if they gave a positive answer to 1 of the following 3 items: being involved in giving intravenous fluids, having worked on a ward where an arrest occurred, and knowing a patient who had undergone an arrest. The close staff group was composed of 43 members and the distant group, 49.

While our hypotheses basically held true for the staff, this did not prove to be the case for the patient group. The close patient group differed dramatically in the opposite direction from what had been expected. This group had more faith in the institution, tended to dismiss the idea of homicide, and was more disapproving of press coverage than was the distant patient group. When we compared the close patient group with the close staff group, with whom they supposedly shared a common environment but were expected to feel even more emotionally threatened because of their medical vulnerability, it was obvious that the two groups were not dealing with the same psychic reality. The close staff group demonstrated increased concern, while the close patient group showed remarkable confidence and faith. This was the exact opposite of what was hypothesized and was interpreted as denial on the part of the close patient group.

Although the trend did not reach statistical significance in the direction opposite that hypothesized, only 16% of the close patient group, compared with 35% of the distant patient group, would have transferred a relative to another facility. However, the staff responded in the expected direction, with 56% of the close group but only 27% of the distant group concerned enough to seek the transfer of a relative ($p<.025$). When the close patient and close staff groups were compared, the difference in the perception of danger in the hospital was even more readily apparent, with the two groups differing significantly in the direction opposite to what was predicted ($p<.005$).

A similar pattern held true for the question as to whether one would be a patient at the hospital in the future. Both patient groups showed nearly unanimous support for the institution (97% close, 86% distant), and the lack of difference between the close and distant patient groups again ran contrary to what was hypothesized. In contrast to the patients, the staff conformed to the hypothesis; only 55% of the close staff and 69% of the distant staff were willing to be a patient at the hospital in the future. The difference in faith in the institution demonstrated by the close patients when compared to the close staff group attending them ironically could not be expressed statistically because too few close patients fell into the category of being unwilling to return to the hospital. The relatively high regard the FBI was held in by patients regardless of category (about 67% overall) and the generally skeptical attitude of the medical staff (about 45% overall) was again evident in question 3.

The most interesting finding was the conception of events that the patients closest to the crisis chose to believe. They did not perceive themselves in danger from a murderer but felt instead that the respiratory arrests were nondeliberate—either coincidence or medical error. Only 35% felt that the cause of the respiratory arrests was deliberate (murder), compared with 69% of the distant patients. This difference was significant ($p<.01$). The distant patient group was apparently reading the papers and watching television and did not differ in its perception of the events from that of the 2 staff groups. Over 70% of both staff groups felt the respiratory arrests were deliberately caused. The perception of events expressed by the close patient group was once more at odds with that of their attending staff, differing in the direction opposite to that hypothesized ($p<.005$). This apparently was denial on the part of the close patients—perhaps the basis of all unrealistically trusting, but sometimes beneficial, "good" doctor-patient relationships.

The response to press coverage again showed the close patient group running counter to the hypothesis and differing from the distant patient group in being less, not more, appreciative of media coverage. Over 65% of the group felt the press exaggerated the situation and did not do either the public or themselves a service. However, the distant patients were more satisfied with the media coverage and saw it as useful; 60% felt that the coverage was not exaggerated ($p<.05$).

Medical staff reaction also ran counter to what had been expected. The close staff did not seem to feel that it had found a mutuality of interest with the media, who also seemed to grasp the gravity of events. Approximately 80% thought the coverage was exaggerated and of no benefit to the patients or public. This did not differ from the view of the distant staff, which was also highly critical. There was a feeling that the press had primarily served itself while serving the public. On this issue the close patient and close staff groups tended to view the situation in a similar manner, since both had a vested interest in dampening the effects of irrational personal panic or public hysteria.

DISCUSSION

Anna Freud (4) described denial as one of the earliest and most basic defensive maneuvers. In its original form, denial is naturally and constructively used by the young child to mitigate and adjust to an external world of powerful, potentially threatening forces with which it is physically unable to cope. Adults also use denial in much the same manner. Aitken-Swan and Easson (5) found that 19% of 231 British cancer patients who had curable lesions of the skin and had been informed of their condition denied having a cancerous condition on re-interview between a week and a month later. Lewin (6) noted the central place of denial in the dynamics of elation in order to generate unrealistic confidence and optimism. Hackett and associates (7–9) found a similar function of denial in the coronary care unit, where denial often served to allay anxiety, maintain hope in a life threatening situation, and generally aid in the patient's acute recovery. They developed a denial scale that was used by Froese and associates (10) in a subsequent study, which found that in the earliest stages of hospitalization for myocardial infarction, patients who used denial tended to gain control over their anxieties sooner than nondenying patients. During the acute stage of the illness, the defense of denial was not as dangerous a mental mechanism as such a blatant distortion of reality characteristically poses over the long term.

Weisman and Hackett (11, 12) explored further the process of denial and its dynamics in another area where it is often used: terminal illness. They saw it not only as a way of avoiding anxiety to one's physical person and internalized self-concept, but also as a positive mechanism for maintaining social contact and relatedness. They stressed the social context under which the denial occurred and the personally constructive ends an individual hoped to pursue by using such a defense. They also drew an important distinction between the process of denying and the act of denial, a distinction that points up the socially determined quality of much of human perception. The process of denying entailed the following four elements: a mu-

tually agreed-upon field of perception, a repudiation by an individual of part of this field of perception, the replacement of this repudiated section with a perception that is more congenial and which reinforces affirmative action, and a reorientation of the individual who has survived for the moment so that he can continue mutual interactions and relationships with others. The act of denial required a fifth step—the judgment by one person upon another that he has denied an event within their common reality. The individual is not aware that he is denying in the present and only becomes aware in retrospect. His principal aim has been to maintain himself and his social relationships.

These elements of the process of denial were very much in evidence among the close patient subgroup in the hospital. A threatening, murderous piece of reality was repudiated and replaced by a more benign view of events. This view of reality helped to ward off anxiety over routine medical procedures and once more allowed affirmative and active cooperation with the medical staff. The continued functioning of the hospital helped to reaffirm their relationship to an institution that had long been a source of medical care and support.

Unfortunately, there are no data on patient and staff attitudes toward the VA system, the FBI, or the media before the crisis. Social class differences alone may account for some of the variance. However, denial mechanisms often protect individuals and social groups from being overwhelmed by anxiety or panic that would otherwise paralyze all functioning and prevent even the initiation of constructive responses. Seemingly, both the close patient subgroup and the staff were critical of media coverage because they saw it as inadvertently, or for its own ends, stirring those forces of personal anxiety and public hysteria that they were attempting to contain. Although the hospital could not do business as usual, with the proper precautions the ill would continue to be cared for and efforts at medical, social, and legal restitution would be begun.

Fortunately, the denial of the patients was accompanied by vigorous preventive measures adopted by the hospital and did not serve as an invitation to further tragedy. While this paper was being written, a federal court issued a 16-count indictment including 5 counts of first-degree murder against 2 nurses who had served on the evening shift in the ICU (13).[1] This by no means marks a legal resolution to the events, since their trial will be closely contested and the eventual outcome is uncertain. However, with the imposition of tighter general security measures, the hospital has returned to normal patient care and functioning.

Early Sexual Experience and Prostitution

BY JENNIFER JAMES, PH.D., AND JANE MEYERDING

The authors compared several aspects of early sexual experience found in two earlier studies of prostitutes with results of research on "normal" women. The prostitutes had in common many negative experiences not found or found less often in other populations of young women. These include incestuous and/or coerced sex, lack of parental guidance, intercourse at a young age, and few or no meaningful relationships with males. These women had discovered that sex could lead to a kind of status, even though that status is negatively labeled by the wider culture. In a society that values women on the basis of their sexuality, a woman who views herself as "debased" may see prostitution as a viable alternative—perhaps the only alternative.

IT HAS BEEN ARGUED by prostitutes and social scientists alike (1, 2) that prostitution is an aspect rather than a contradiction of the female sex role in our society. What then determines which women will act out the prostitution components of that role? According to Rosenblum (2), "access to prostitutes and perhaps specific incidents in the life of the individual" are the deciding factors. One of us (J.J.) conducted studies of streetwalkers in a large western city that seemed to indicate a common pattern of certain sexual experiences—many of them negative—among the 228 subjects studied (3, 4). Although there is more to the profession of prostitution than just sex (e.g., economics, customer demand, a subcultural ethos), it seems clear that a woman's self-concept of her sexuality must play an important part in her decision to prostitute and that sexual experiences unrelated to prostitution may have considerable impact on the development of this self-concept. In this article, we will present data on the sexual experiences of subjects in these two studies that we feel may be particularly relevant to the development of the deviant self-image of "prostitute." The experiences we will consider are age at first intercourse, early sources of information about sex, subsequent relationship with first sexual partner, number of sexual partners, number of "significant relationships," incest, and rape.

Both studies involved questionnaires, interviews, and ethnographic field observation; thus, data are limited to "self-report." The first study (referred to as study 1) was conducted between 1970 and 1972 with a sample of 72 adult prostitutes and 20 adolescent prostitutes contacted on the street and in jail (3). The second study (study 2), conducted during 1974–1975, included 136 prostitutes contacted in the same way; 68 of these subjects were also defined as addicts (4). In order to make our data more meaningful, we will use comparisons with studies of "normal" female sexual experience.

AGE AT FIRST INTERCOURSE

It is difficult to compare data from different studies on age at first intercourse because of varying methods of data presentation. For example, Sorensen's data (5) on age at first intercourse do not differ significantly from the results in study 2 except that a larger number of subjects in the latter study had their first intercourse at age 12 or younger (13% versus 7%). However, since 48% of Sorensen's total sample had not had intercourse, we can conclude only that there seems to be a section of the general adolescent population, of which the subjects of studies 1 and 2 are members, who are more sexually active at an earlier age than the norm.

Other studies support the conclusion that our subjects initiated sexual activity at a younger age than the general population. Kantner and Zelnik (6) compared age at first intercourse for the black and white members of their sample. They found that 54% of their black subjects experienced first coitus between the ages of 15 and 19 (74.9% of them by age 18), whereas only 23% of the white subjects had their first experience at those ages (19.9% by age 18). In the study 2 population, 56.6% reported first intercourse between the ages of 15 and 19 (36% had had intercourse before that age), and 91.9% of the sample had had coitus by age 18. In striking contrast is the figure of 17% nonvirgins at age 18 found by Simon and associates (7) in a sample limited to college students. Four-fifths of the adolescents in study 1 had their first sexual intercourse at age 14 or younger. Although information on sexual experiences before first intercourse was not elicited in the questionnaires in studies 1 and 2, extensive interviews revealed a pattern similar to the one found by Davis (8)

The authors are with the University of Washington, Seattle, Wash. 98915, where Dr. James is Associate Professor, Department of Psychiatry and Behavioral Sciences, and Ms. Meyerding is Research Analyst, Female Criminal Involvement and Narcotics Addiction project.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant DA-00918 from the National Institute on Drug Abuse.

in her study of 30 prostitutes: "The 'technical virginity' pattern typical of the middle-class female was not in evidence here. First sexual contacts typically involved sexual intercourse, with only one girl reporting an initial petting experience."

EARLY SOURCES OF INFORMATION ABOUT SEX

The first questions relating to sexual history in studies 1 and 2 attempted to elicit the subjects' major sources of early information about sex. In study 1 (3), 63.2% of the adolescent subjects—toward whom the questions on sexual history were aimed—learned about sexual intercourse from friends (36.9%) or personal experiences (26.3%). Study 2 produced more detailed information (4). The role of parents as sex educators was considerably less in study 2, the more recent sample, than in Wittels' 1951 study (9) (15.4% versus 34%). Friends continue to be the major source: Wittels found a figure of 42.7% and the study 2 figure was 37%, Adding the study 2 category of "siblings" to that of "friends" to produce an "other children" grouping increases the figure for this category to 44.9%. The role of teachers in sex education was somewhat smaller in study 2 than in Wittels' study (5.9% versus 9%), as was the influence of physicians (1.5% versus 3%). Wittels' final category, "other adults," has no counterpart in study 2. The 17% Wittels found in this category must balance against the categories of "books," 10.3%; "church," 0.7%; and—perhaps the most significant difference from Wittels' study and a possibility he apparently did not consider—"personal experience," 14%. Sorensen (5) found that 31% of his sample had learned about birth control and 33% about venereal disease from their parents. These figures approximate Wittels' 34% figure for the role of parents and reemphasize the contrast with the study 2 finding of 15.4%. The close agreement between Wittels' and Sorensen's data on this point is particularly striking given that the former study was conducted in 1951 and the latter in 1973.

This lack of parental guidance in sexual matters is one aspect of the general weakness of the parent-child relationship that is typical of many prostitutes (8, 10–16). Whether the parent-child relationship is marked by simple neglect by absence or by outright psychological or physical abuse, the result for the child is generally considered to be alienation from the parents and a consequent inability—the severity of which depends on the circumstances—to adequately socialize the conventional mores of "respectable" society.

SUBSEQUENT INTERCOURSE WITH FIRST PARTNER AND NUMBER OF SIGNIFICANT RELATIONS

The use of different groupings (e.g., "5 to 6 times" versus "5 to 10 times") makes it difficult to do a strict statistical comparison of the number of times subjects in various studies had intercourse with their first coital partner. It seems obvious, however, that the most significant difference between the results in study 2 and those from studies of "normal" populations is the percentage reporting no further intercourse with their first partner. In study 2, 33.8% reported they had no further sexual relationship with their first partner, whereas other studies found figures of 10%–15%. Table 1 compares findings from study 2 with those of Eastman (17).

TABLE 1
Subsequent Intercourse with First Coital Partner

	Eastman (17) (N=43)		Study 2 (4) (N=133)	
Frequency	Number	Percent	Number	Percent
Never again	6	14.0	45	33.8
1–2 times	6	14.0	15	11.3
3–10 times	12	27.8	25	18.8
11 or more times	19	44.2	48	36.1*

*Includes categories: "11–20 times," 8.3%; and "regularly," 27.8%

TABLE 2
Number of Sexual Partners in Two Samples of Women*

	Kinsey and Associates (18) (N=1220)		Study (2) (N=135)	
Partners	Number	Percent	Number	Percent
1	647	53	4	3.0
2–5	415	34	25	18.5
6–10	85	7	37	27.4
11–20	49	4	22	16.3
21 or more	24	2	47	34.8

*Customers are excluded in figures for study 2.

That the superficial, nonemotional nature of the first sexual intercourse of many of these women initiated a series of such encounters is supported by the fact that the mean number of private (i.e., not for profit) sexual partners of subjects in study 2 was 23. Even more significant is the fact that the mean number of persons with whom these subjects felt they had developed a "significant relationship" was only 5: 17.8% reported more than 10 and 71.6% reported 5 or less. Table 2 compares data from study 2 on numbers of sexual partners with data from Kinsey and associates (18).

INCEST AND RAPE

In their 1953 report on female sexuality, Kinsey and associates (18) found that 24% of their sample had experienced at least one sexual advance by an older male (defined as being at least 5 years older than the subject); they stated that the percentage would have been greater if the sample population had included more

TABLE 3
Adult Perpetrators of Sexual Advances Toward Children

Adult	Kinsey and Associates (18)		Gagnon (19)		Study 2 (4)		De Francis (20)	
	N	%	N	%	N	%	N	%
Stranger	559	48.7	195	58.5	13	20.6	63	25.0

Foster father	—	—	—	—	3	4.8	—	—
Other relative***	204	17.7	45	13.5	7	11.1	28	11.0
Total	1150		333		63		252	

*In Study 2, the category was "family friend."
**De Francis' category was "parent surrogate." Offenders were virtually all male.
***Kinsey's categories included "uncles," 9%; "brothers," 3%; "grandfathers," 2%; "other relatives," 5%.

lower-class respondents. This figure and Gagnon's later figure of 28% (19), contrast sharply with the findings in study 2: 46% responded affirmatively to the question "Prior to your first intercourse, did any older person [defined as more than *ten* years older] attempt sexual play or intercourse with you?"

Kinsey and associates (18), Gagnon (19), and De Francis (20) attempted to ascertain the relative incidence of participation by various categories of males in such sexual advances (see table 3). Comparing data from study 2 with those of Kinsey and associates and Gagnon, it is apparent that the findings in the categories of "strangers" and "father figures" are very different: 3.7% of the perpetrators in Kinsey's study and 1.5% in Gagnon's work were fathers, whereas study 2 found that 25.5% were fathers, stepfathers, or foster fathers. Combining the percentages of fathers and "other relatives" in these three studies gives the following totals for sexual experiences with an "incestuous" character: Kinsey and associates, 21.4%; Gagnon, 15%; and study 2, 36.6%.

De Francis' data more closely approximate those from study 1. He found that 27% of such offenders were father figures; 38% were relatives.[1] In study 1, 13 of the 20 adolescent subjects reported having had a "forced/bad sexual experience,"[2] the majority of which (11 of 13) occurred when the subject was 15 or younger. In many cases the men responsible were fathers (23.1%) or other relatives (15.4%). Of the total sample of 20, one-fourth had experienced a negative sexual relationship with a relative. Sgroi (21) also reported that "The most frequently named perpetrator in cases of sexual abuse (of children) is the father or a male relative or [mother's] boyfriend."

None of the studies of "normal" female sexual experience available for comparison included statistics on the number of subjects who experienced the use of force in their first intercourse. In study 2, 23% of the subjects reported that they had been subjected to physical force in their first intercourse, and 7.4% felt they had been victims of emotional coercion. More than half (57.4%) of the study 2 sample reported that they had been raped at least once in their lives. Of these, 36.2% had been raped more than once, and 7.5% had been raped by multiple assailants.

DISCUSSION

Societal reactions to juvenile female sexual activity may influence the entrance of some young women into prostitution, especially those who are more sexually active and less discreet than the majority of their peers, as seems to have been the case with the subjects in studies 1 and 2. Choisy (11) asked, "At what number of lovers is a girl supposed to lose the status of a decent person?" Carns (22) stated that "A woman's decision to enter coitus . . . implies that she is creating for herself a sexual status which will have a relatively pervasive distribution . . . she will be evaluated downwardly. Such is the nature of the male bond." Girls learn early society's moral valuation of their sexuality. For example, in discussing her childhood sex education, one streetwalker stated, "I think the basic theme of the whole thing was that it was a dirty thing but that it was a duty for a woman to perform, and if you fooled around, you were a prostitute." Female promiscuity, real or imputed, virtually guarantees loss of status in our majority culture: one hears such statements as "I got pregnant and was kicked out of the house and school" or "I was accused of being promiscuous while I was still a virgin. They did that because I used to run around with a lot of guys." The labeling implied by such loss of status may be an important step in the process by which a woman comes to identify with a deviant lifestyle such as prostitution and thus begins to see it as a viable alternative. Davis (8) described this process in her discussion on the effects of institutionalization:

[1]It should be noted that De Francis' sample population is strongly biased in the opposite direction from those of Kinsey and associates and Gagnon, i.e., toward the lower class, and his sample consisted of "cases" serious enough to come to the attention of police or child protection agencies.

[2]Sexual experience is defined as intercourse. The force involved included both physical and emotional coercion in which the subject's self-report indicated she was sexually used against her will.

> The adolescent girl who is labeled a sex offender for promiscuity . . . may initially experience a conflict about her identity. Intimate association with sophisticated deviants, however, may provide an incentive to learn the hustler role . . . and thus resolve the status anxiety by gaining prestige through association with deviants, and later, experimentation in the deviant role. (8, p. 305)

Even in noninstitutionalized women, the labeling impact of status loss must have a strong effect on self-image. The woman may attempt to rebuild her self-image by moving into a subculture where the wider society's negative labeling will not impede her efforts toward a higher status—although that status itself will be perceived as negative by the wider society. Of the prostitutes in study 2, 44.9% reported that they had "gotten into trouble" because of their sexual activity while they were juveniles.

No matter how negative the long-term effects of juvenile promiscuity on a woman's social status are, the short-term effects may often seem quite positive to her. Young women who suffer from parental abuse or neglect, a common pattern for prostitutes, may be especially susceptible to the advantages of what Greenwald (15) called "early rewarded sex . . . engaging in some form of sexual activity with an adult for which they were rewarded. [These women] discovered at an early age that they could get some measure of affection, of interest, by giving sexual gratification." This type of positive reinforcement for sexual behavior, particularly when coupled with the cultural stereotype of women as primarily sexual beings, may cause some women to perceive their sexuality as their primary means for gaining status. Davis noted that "Sex as a status tool is exploited to gain male attention" (8). All women in our culture must in some way come to terms with the fact that their personal value is often considered inseparable from their sexual value.

> While men are also concerned with their sexual desirability, their opinion of themselves is not founded primarily on that desirability, for occupational achievement provides an important alternative to a self-identification based on sexual desirability. The alternatives available to females are fewer and generally carry lower social esteem, resulting in an inordinately high value being placed on sexual desirability. (2, p. 180)

The effect of incest on the child involved is virtually unknown. Some researchers, e.g., Jaffe and associates (23), preferred not to make a judgment, noting that "Little is known of the physical and emotional effects of incest." Ferracuti (24) stated that "it is hardly proved that participation in incest . . . results in psychological disturbances." He noted, however, that "Frequently [victims of incest] become sexually promiscuous after the end of the incestuous conduct." De Francis (20) found guilt, shame, and loss of self-esteem to be the usual reactions of the child victims of both incestuous and nonincestuous sex offenses. These feelings often led to disruptive, rebellious behavior, and some older (i.e., adolescent) victims later become prostitutes. Sexual abuse that continues over a long period of time, as is usual with incest, was found by Gagnon (19) to be "extremely disorganizing in its impact" on the victim. Weiner (25) echoed Ferracuti in stating that "girls who begin incest in adolescence frequently become prostitutes following termination of the incest."

The incidence of rape experiences among the study 1 and study 2 populations, especially among the adolescents in study 1, is so high that these samples present the characteristics of an especially victimized group. Although the subjects' identities as rape victims or nonrape victims were not in any way considered in the sampling procedures, 65% of the adolescent prostitutes had been the victims of coerced sexual activities. The 57.4% of the study 2 sample who had experienced rape, including 36.2% who were multiple rape victims, is also disproportionate compared with wider samples of women. When the societal stereotyping of women as primarily sexual beings is expressed through the violence of rape, the psychological effect on the victim may be one of reinforcing her self-concept as a sexual object and further isolating her emotions from her sexuality.

CONCLUSIONS

The prostitutes in the two studies we have considered shared a range of negative sexual experiences that—in conjunction with other circumstances and experiences—may have influenced them toward accepting prostitution as a lifestyle. The pattern that emerges includes 1) lack of parental guidance that leads to early, casual sexual intercourse to the exclusion of the more usual noncoital sociosexual experimentation; 2) the discovery that sex can be used to gain a kind of social status, coupled with the subsequent discovery that this status is perceived by others as negative, making the individual unacceptable to the majority culture; and 3) the emotionally destructive experiences of incest and rape. Because the range of acceptable sexual behaviors is much narrower for women than for men, and because women more than men are judged (by themselves and by others) on the basis of their sexual desirability and behavior, sexual experiences may be a more important factor in a woman's development of self-identity. A woman who views herself as sexually debased or whose sexuality is more than normally objectified may see prostitution as a "natural"—or as the only—alternative.

Planning for a Mental Hospital Phasedown

BY M. POWELL LAWTON, PH.D., MORTIMER B. LIPTON, PH.D., MARK C. FULCOMER, PH.D., AND MORTON H. KLEBAN, PH.D.

The authors studied the patients and community facilities in an area for which a mental hospital phasedown was contemplated. They found that patients who were continuously hospitalized during a 9-month period were highly dependent and judged unlikely to be candidates for community placement. By contrast, the patients who had been discharged during this 9-month period were judged relocatable by staff and constituted a select group in terms of independence. The authors' survey of community facilities indicated few placement possibilities for the majority of the continuously hospitalized patients.

CONCEPTS OF WHAT constitutes desirable treatment for the psychiatrically disturbed have changed greatly since the publication of the report of the Joint Commission on Mental Illness and Health in 1961 (1). Realization of the deficiencies of public mental institutions led to the creation of the community mental health network and the search for community-based alternatives to institutionalization. Over the past decade a massive effort to deinstitutionalize psychiatrically disturbed patients and to forestall the admission of new patients has been made, resulting in an overall reduction of the public mental institution population from 527,000 in 1961 to 338,000 in 1970 (2), even though as of 1973 only 12 state hospitals had closed completely (3).

The consensus of most mental health professionals is that the emphasis on community-based treatment has been well placed. On the other hand, many problems associated with the deinstitutionalization process have arisen. "Community placement" has often meant transfer to nursing homes or boarding homes in which the environment is impoverished at best and more dehumanized than many mental hospitals at worst (4–6). Many reports, including those in the popular media, have also called attention to the isolation of the ex-patient and the failure of the community mental health system to provide services for the many ex-patients who live alone after their discharge from the hospital (4–6).

The concentration of large numbers of ex-patients in certain neighborhoods has created many problems for other community residents and has sometimes led to a backlash of attempted restrictive zoning and other unwelcoming behavior (4). Although a number of studies have suggested that there are positive outcomes associated with favorable community placements during a hospital's phasedown or closing (7, 8), national trend data showing increases in inpatient episodes (9) and in readmissions (3) suggest that there is some reality to the idea that the "revolving door" has replaced continuous institutionalization as the norm for chronically ill patients.

Policy that makes mental hospitalization more difficult has in some instances forced mentally ill patients to use acute-hospital care, which is far more expensive, for longer periods than necessary (6). There is some evidence to suggest that the shock of transfer itself has negative consequences in health and mortality for elderly mentally ill patients (10, 11), but this is not a consistent finding (12). In some cases, an interinstitutional transfer appears to stimulate later community placement (13). A comprehensive review of these and other issues may be found in *Deinstitutionalization* by Bachrach (14).

The point of this brief review is to suggest that there are enough negative features associated with phasedowns of mental hospitals to warrant giving increased attention to averting problems. Despite the fact that phasedowns have been implemented, there are few firm research findings to document the frequency with which problems have occurred or to assess long-term consequences for patients, communities, and treatment systems.

There are few reports on the processes by which large-scale movement of patients out of hospitals has been accomplished, and fewer yet on the use of ongoing data systems as the basis for planning. In this re-

Drs. Lawton, Fulcomer, and Kleban are Medical Research Scientists and Dr. Lipton is Director, Program Research Unit, Norristown State Hospital, Norristown, Pa. 19401.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-17473 from the National Institute of Mental Health, by the Northeast Pilot Project of the Pennsylvania Department of Public Welfare, and by Norristown State Hospital.

The authors would like to thank Frank S. Beal, Secretary, Pennsylvania Department of Public Welfare; Robert M. Daly, current Deputy Secretary of Public Welfare and Commissioner of Mental Health; and James R. Harris, M.D., former Deputy Secretary of Public Welfare and Commissioner of Mental Health and current Superintendent, Norristown State Hospital. They would especially like to thank Kathryn S. McKenna, Deputy Secretary of Public Welfare; Sylvia Green, Coordinator of the Northeast Pilot Project; Emily Meyer; George E. Gittens, M.D.; and Jule Wnorowski. Linda Shoemaker was responsible for project coordination at Norristown State Hospital and for the preparation of the STEP manual. Statistical and application programming was done by Ferne Kleban. Data analysis and statistical tabulations were done by Linda Shoemaker, Carolyn Parkes, and Marsha Kness.

port we will describe the beginning of an effort to phase down an institution, highlighting the use of a formal program evaluation structure as the basis for decisions regarding the feasibility of the plan. We will emphasize some of the limitations of the specific method used in the hope that improvements might be incorporated into future efforts.

This research was done by the Program Research Department of Norristown State Hospital at the request of the Pennsylvania Department of Public Welfare to provide information regarding the feasibility of at least a partial phasedown of a 550-bed state hospital (not Norristown State Hospital). The physical facilities of this hospital were for the most part very old; it would be possible to bring them up to code requirements only at great expense. The hospital served two counties with a population of 361,000 that contained one moderate-sized city, several small cities, and a large rural area.

The task was defined as the determination of the number of currently hospitalized patients for whom an alternative other than the state hospital might be feasible and the types of non-state-hospital alternatives available in the geographical area.

The data on patients were obtained using the Systematic Treatment Evaluation Procedure (STEP), a psychometrically derived rating document designed to obtain information regarding each patient's current mental, physical, and behavioral status; current diagnosis; current and recommended referrals and services; estimated date of separation from the institution; and eventual expected residential location. The STEP has been described in greater detail by Lipton and Hespenheide (15), Fulcomer (16), and Kleban (17) as a component of an integrated treatment-oriented data system.

The STEP forms were completed by the treatment-unit team for 550 patients who were hospitalized continuously from May 1, 1975, through February 28, 1976, and for 104 patients who were discharged during that period. This represents all of the patients in the hospital during this 9-month period except for those who died before February 28, 1976, and 14 patients who were discharged before STEP ratings could be completed. All of the staff presumably knew about the potential closing of the hospital and had direct contact with the program research staff during the data-gathering period.

The primary purpose of the STEP document was to give a descriptive picture of the universe of patients, including those for whom relocation was a possibility.

CONTINUOUSLY HOSPITALIZED PATIENTS

The diagnoses of 531 of the continuously hospitalized patients are shown in table 1. Because of the probability that patients under 21 years old (N=8) and those hospitalized under a criminal court commitment (N=10) would have a short hospital stay, these patients were not classified by diagnosis. Among patients classified as psychotic (primarily schizophrenic, depressive, and manic-depressive psychoses), we made the further distinction between the 92% who were receiving continued treatment and the 8% who were receiving intensive treatment. A patient was considered to be receiving intensive treatment if he or she had either been hospitalized for less than 1 year or if the estimated date of separation was 1 year or less.

TABLE 1
Primary Diagnoses (N=531)* and Optimal Residential Expectations (N=550) for Patients Continuously Hospitalized for a 9-Month Period

Item	Number	Percent
Diagnoses		
Psychosis	352	64
Organic brain syndrome	111	20
Mental retardation	51	9
Psychoneurosis	8	1
Personality disorder	9	2
Optimal residential expectations		
Not in mental hospital		
Patient's own home	24	4
Home of relatives or friends	53	10
Supervised residence	48	9
Foster home	37	7
Long-term care facility	30	5
Other institutions	12	2
Other	1	
Total	205	37
In mental hospital		
Remain in same mental hospital or go to another	182	33
Not likely to leave hospital for any reason	163	30
Total	345	63
All continuously hospitalized patients	550	100

*Excluded are 8 patients under the age of 21 (1% of all 550 patients); 10 patients hospitalized by criminal court order (2%); and 1 patient whose diagnosis was missing.

Less than 2% of the continuously hospitalized patients were under 21 years old; 35% were 65 or older. Of the 325 psychotic patients receiving continued treatment, 56% were 65 or older, and 70% of the patients with organic brain syndrome were in this age range.

On a 7-point rating scale of general health on which 1=no apparent problem and 7=problem of devastating proportion, 29% of the 550 patients had a rating of 4 (relatively severe problem) or more in general physical health.

Two aspects of independence were rated on 5-point scales ranging from totally dependent to totally independent: capacity for basic self-care and degree of residential supervision required. Ratings on these two scales were combined into a single 4-point dependency rating: 1=very highly dependent (42% of the continuously hospitalized patients); 2=highly dependent (27%); 3=moderately dependent (20%); and 4=minimally dependent (11%). The patient population was thus highly skewed in the direction of dependency (median rating=1.8). The concurrent validity of the dependency rating was demonstrated by its highly sig-

nificant correlations with factor scores of cognitive status, withdrawal, self-care ability, disorganized communication, and social activity derived from STEP clinical ratings of 72 highly specific behavioral and symptom manifestations (16).

The treatment teams were asked to make estimates of each patient's probable date of separation on the basis of the patient's current condition, past history, and the possible environmental opportunities. The task was phrased in this manner to concretize the judgment of prognosis and thereby encourage maximum discrimination over a wide range of favorable to unfavorable prognoses. Eighteen percent of the 550 patients were judged likely to be able to leave the hospital within the earliest possible time frame for mass relocation (1 year), 23% after 2 years, and 29% after 3 years. Sixty percent were judged never likely to separate. Thus, staff were generally pessimistic about separation; this was consistent with their ratings of dependency.

The staff were also given a checklist of 25 possible residential locations (plus spaces for "other") to which a patient might be transferred should he or she leave this state hospital. Since one or more locations could be checked, the optimal choice was considered the one allowing the highest level of independence, as determined by research staff ratings of the whole list in terms of the degree of independence afforded in the average living situation represented by each choice. Only 37% of the 550 patients were judged capable of ever leaving a mental hospital (see table 1). Since "mental hospital" was listed as a residential expectation, separate figures are shown for this alternative and for when no change in type of residence was expected, although there is no substantive difference between these two categories.

DISCHARGED PATIENTS

During the 9-month study period, 104 patients were discharged to locations other than mental hospitals. These patients were also evaluated by the STEP document, but they are not included among the 550 continuously hospitalized patients. Eighty-eight percent of the 104 discharged patients had been judged capable of leaving the hospital within 9 months or less, a finding that supports the validity of the expected date of release estimate. Of the 104 discharges, 65% were to relatively "easy" placements, i.e., to their own home or the home of relatives. The median length of hospitalization of all 104 discharged patients was 11.3 months, and their median dependency level at the time of initial STEP evaluation was 3.1 (slightly better than moderately dependent), compared with the median of 1.8 for the 550 patients who stayed in the hospital during the study period. These figures demonstrate that patients who were discharged had short-term illnesses, were considered the most independent, and had environmental supports available.

In summary, the treatment team's assessment of the functional capacity and symptoms of the patients who were continuously hospitalized and of those who were discharged during the study period clearly documents the very low level of independence of the great majority of patients and the highly selected characteristics of those who were discharged.

AVAILABLE COMMUNITY ALTERNATIVES

We also surveyed existing facilities for discharged mental hospital patients for relocation possibilities. The social service personnel of the hospital compiled a list of all of the facilities in the two-county area that were known to have accepted discharged patients recently and were potential service resources. The survey thus omitted an unknown number of facilities that had not been used because they were of poor quality, charged fees that were beyond the state's or the patients' financial resources, or simply had not been discovered as possible resources.

A social worker or research assistant visited each facility and conducted a structured interview with the administrator or owner regarding administrative practices, staffing, treatment programs, physical features, finances, and policies regarding the acceptance of clients. There were 23 foster homes in the area, representing a combined resident capacity of 61 with 15 vacancies; 24 supervised residences, representing a capacity of 471 with 78 vacancies; and 22 long-term care facilities, representing a capacity of 1,469 with 56 vacancies.

Comparison of the number of vacancies (N=149) with the number of patients judged suited for placement in a foster home, supervised residence, or long-term facility (N=115; see table 1) indicates that, with the exception of foster homes, there are enough vacancies (other institutions such as medical hospitals, institutions for the retarded, or rehabilitation hospitals were not included in this survey of facilities). However, responses to a series of questions regarding possible criteria for excluding admissions revealed many reasons to expect great difficulty in matching a placeable patient with an available space.

Twenty-six of the facilities admitted either only men or only women; 3 would not admit patients who were mentally retarded; 65 excluded some patients on the basis of the degree of their mental illness; 27 excluded patients who were not ambulatory; 24 excluded patients who were not able to take care of themselves; 24 would not admit substance-abusing patients; 45 excluded patients with particular physical illnesses or disabilities; and 18 had other excluding criteria. No facility was without such restrictions, and most reported more than one criterion for exclusion.

One can see that the number of reported vacancies actually available for placement is drastically reduced if the exclusions are taken into account. This number would again be reduced by considerations not covered

in the present study, such as patient preference, relatives' preference, cost of the placement, and geographic location. The only factor that might operate to increase the number of placement opportunities would be the addition of new facilities, the discovery of additional existing facilities, or the active promotion of such additional resources as foster homes.

DISCUSSION

To summarize our major findings: 1) the great majority of patients served by this state mental hospital were highly dependent, long-term, chronic, and elderly; 2) a minority (18%) were judged capable of living in a location other than a state mental hospital within a period of 1 year; 3) the population actually discharged was primarily an acutely ill, relatively recently admitted group; and 4) existing community facilities would be hard put to accommodate even the small number of patients with the best prognoses. The deficits among the large majority of patients would almost certainly preclude their acceptance by any community facility.

These conclusions are entirely consistent with those of Deasy and Steele (18) in a study of the community residence potential of mental hospital patients in Florida. They also found an excess of demand over supply in both community mental health facilities and nursing homes.

Perhaps the most vulnerable point in this study is the fact that the source of much of the data was a group of employees whose jobs had been threatened and who knew that the survey results would be relevant to the ultimate outcome of the threat. Fortunately, the 72 clinical ratings of the STEP document had been used about 18 months earlier in large representative patient samples (N=747) from three other hospitals in the state system that have never been mentioned as candidates for the phasedown program. The levels of rated psychopathology in these nonthreatened hospitals (mean standardized factor score=2.837) were virtually identical to those found in the targeted hospital (mean=2.803). If bias had been present, mental state would surely have been judged poorer in the threatened hospital.

It was also impossible to make a specific estimate of the number of patients who could be accommodated in each type of facility or to make a projection of the number of additional resources that would be required over the next few years to accommodate the eligible patients. This gap was purely a matter of limited research resources. It is entirely within the capability of a larger research project to obtain more detailed patient and facility information and a near-100% sample of all facilities and to match individual patients with individual facility types, taking account of specific admission policies. These data would provide valuable information for short- and long-term planning.

This picture can never be complete without considering patient and family preference, the constraints of distance, and the financial matching of payer and vendor. Finally, considerable sharpening of our ability to measure the quality of treatment will be necessary before we can know whether a particular type of facility can really deliver the care needed by a specific patient. The matching of patients to facilities chosen without reference to their quality clearly risks mismatches.

Given the above limitations, one may conclude that this study of patients and community facilities gives considerable reason for caution in the planning of mental hospital phasedowns. One simply cannot wish out of existence the realities of chronic psychosis and chronic patienthood on the one hand and the short supply of community placement possibilities on the other, to say nothing of the deprived environments of many community facilities. The hard line of the past decade on institutionalization has unquestionably had a favorable effect on the unnecessary incarceration of large numbers of people. Although our data suggest that there is still a gap between the number of patients who are capable of living in the community and the number of opportunities for community living, the gap has greatly narrowed. The tasks for the future seem to be to close this gap completely by improving the quality of alternative treatment environments that are now so poorly serving patients released to the community and to relinquish the fantasy that all patients are better served in the community.

Social Disability in Chronic Psychiatric Patients

BY JUDITH A. SYLPH, M.A., DIP.SOC.ADMIN., HELEN E. ROSS, B.A., B.J., AND HENRY B. KEDWARD, M.D.

The authors measured the social functioning of 147 chronic psychiatric patients using a rating scale originally devised for use with the mentally retarded, the Adaptive Behavior Scale (ABS). They found that social deficits were more widespread and generally more severe among chronic psychiatric patients than among institutionalized mentally retarded subjects. Chronic undifferentiated schizophrenic patients showed the most comprehensive deterioration; other groups, such as neurotic patients, women, and the elderly, had more limited impairments. The authors suggest that the ABS can be useful in establishing the limits of social functioning of chronic psychiatric patients.

SINCE THE ADVENT of community psychiatry, it has become commonplace for chronic psychiatric patients to be discharged from mental hospitals. Adequate preparation for discharge is critical for this type of patient, whose social skills may be atrophied or geared to the expectations of the chronic ward. Comprehensive patient evaluation is essential to rehabilitation planning and should include assessment of social functioning to measure patients against community norms. Quantifiable social data that are detailed and specific can contribute significantly to the choice of rehabilitation program. The study reported here measured the social functioning of a group of chronic psychiatric patients with a rating scale particularly suited to a population deficient in social skills, having been devised originally for use with the mentally retarded.

METHOD

We studied the social functioning of 147 chronic psychiatric patients from two mental hospitals in Toronto. Patients were aged from 25 to 65, were currently in full-time care, and had spent a minimum of two years in a hospital or alternative residential psychiatric facility.

Psychiatric diagnoses were made by research psychiatrists using the Present State Examination (1). Schizophrenia was divided into three subgroups—chronic undifferentiated, differentiated syndrome, and residual—according to *ICDA-8* criteria (2).

Social functioning was evaluated with the Adaptive Behavior Scale (ABS) (3), selected for its comprehensiveness, its specificity, and the appropriateness of its threshold. Below an upper limit of "normal" socially acceptable behavior, a broad range of deviant or socially conspicuous behaviors can be rated. The first part of the ABS (Part I) assesses instrumental daily living skills; the second (Part II) assesses interpersonal and expressive behavior. General categories of behavior (called "domains") comprise a number of individual items whose ratings are added together to form a domain score. ABS assessments were carried out mainly by psychiatric nurses who knew the patients well and who had received instruction in the use of the scale.

RESULTS

Individual Items of Behavior

For the most part the results reported refer to the domains of behavior (see tables 1 and 2). However, a clearer picture of the group's social functioning can be gained from the individual items making up the domains.

On Part I of the scale, over half of the 60 items assessing daily living skills were found to be beyond the capacity of at least 50% of the chronic psychiatric patients. One third of the patients had distasteful table manners. Almost all could dress and undress, but without supervision many would attract unfavorable attention in the community. About half were unkempt, were inappropriately attired or groomed, or would go about dirty unless reminded to wash. A slightly smaller proportion could not take a bath unaided, and 30% were unable to wash their hands and face adequately. A quarter wet or soiled themselves at least occasionally, and about 20% needed help at the toilet. Over three-quarters could not manage money satisfactorily, 57% had difficulties with public transportation, and almost half were unable to use the telephone or find their way about outside the hospital.

Impairment of work capacity was marked. Poor performance of domestic chores was universal, and only a third of the patients managed other types of work. Common types of work failure are suggested by the

Ms. Sylph is Research Scientist, Ms. Ross is Research Assistant, and Dr. Kedward is Professor of Psychiatry and Head, Psychiatric Epidemiology Section, Clarke Institute of Psychiatry, 250 College St., Toronto M5T 1R8, Ont., Canada.

prevalence of slow and sluggish movements and lack of initiative, perseverance, and organizing capacity among 58%–75% and unreliability in carrying out assignments in 96%.

Between 10% and 30% of the patients had defects of sight, hearing, mobility, or manual control, and the body balance of 79% was rated as impaired. Language and communication handicaps were common: 10% of the patients were mute or unintelligible and a third had blocked or unclear speech. Vocabulary and sentence construction were severely limited in 60%–75%. One third could not understand complex instructions, and twice as many had difficulty reading.

On Part II of the scale the most prominent characteristics were in the domains of rebellion, withdrawal, and psychological disturbances. About half of the patients resisted instructions, ignored regulations, or neglected assignments. Over a third misbehaved in group settings, and a quarter ran away. Half of the patients were unable to tolerate frustration, 44% exhibited emotional instabilities, 41% demanded excessive attention, 37% resented criticism, 33% had outbursts of temper, 38% were violent, and 39% used profane, hostile language. Around 20% engaged in other forms of antisocial behavior, such as teasing others or disrupting their activities. Thirteen percent did physical violence to themselves.

The majority of the patients were described as withdrawn, 42% as profoundly withdrawn and inactive, and 40% as withdrawn but active. Bizarre, psychotic behavior occurred in various forms: over 40% had inappropriate interpersonal manners or disturbing vocal or speech habits, 37% performed stereotyped actions, and roughly 20% showed other oddities of behavior, such as chewing clothing or smelling everything. Sexually aberrant behavior was uncommon; between 2% and 8% of the patients were rated positively for each of the four items in this domain.

Social Functioning by Behavioral Domain

Tables 1 and 2 show the mean scores for the behavioral domains. For the purpose of comparison the optimal score for each domain is presented, together with the scores of a group of institutionalized mentally retarded adults of comparable age and IQ range derived from the data of Nihira and associates (4). No scores on normal adult populations are available. We emphasize that optimal score represents only the minimum social performance compatible with community survival.

On Part I the chronic psychiatric patients functioned at a consistently lower level than the mentally retarded subjects; the differences reached statistical significance in 9 out of the 10 domains (see table 1). The patients' best ratings were in physical development, number and time concept, and independent functioning, which covers personal care activities, and their worst were in domestic occupation, responsibilities, and socialization.

The results for Part II are presented in a different manner (see table 2) because of the difference in scoring method. Unlike Part I, high scores on Part II are indicative of maladaptive behavior; the optimal score for each domain is zero. The percentage of patients and mentally retarded subjects receiving adverse ratings and the mean scores of those who scored more than zero are presented in table 2.

Of the two groups, the proportion of psychiatric patients receiving adverse ratings was larger on all but two domains, and the differences were statistically significant on seven (see table 2). However, when subjects in the two groups who scored more than zero were compared, the retarded subjects received somewhat poorer ratings on the majority of Part II domains, although the differences were not tested statistically because the variance of the scores in the retarded population was not available. Thus, although behavior disturbance was more widespread in the chronic psychiatric patients, it was not usually more severe.

The patients' worst ratings were obtained on rebellious behavior, psychological disturbances, and withdrawal, in which the largest proportions of patients receiving adverse scores were also found.

Differences in Social Functioning Between Groups

Sex. Although there was a consistent trend for women to receive worse ratings on both parts of the ABS, this is largely a function of the greater age of the women. When age was controlled for, women performed significantly worse than men on only four domains, violent and destructive behavior, untrustworthy behavior, inappropriate interpersonal manners, and psychological disturbances. Women performed better on one domain, domestic occupation.

Age. Statistically, increasing age was correlated negatively with physical development, independent functioning, and economic activity. Older patients were also rated as more eccentric but less rebellious, less sexually aberrant, and less psychologically disturbed than younger patients.

Diagnosis. Differences between diagnostic groups were statistically significant for all Part I domains. The best scores were obtained by neurotic and affective patients throughout Part I, with the exception of physical development, general occupation, responsibilities, and self-direction, on which residual schizophrenic patients were rated best. Patients with organic syndromes or chronic undifferentiated schizophrenia were consistently placed last or next to last as least socially competent.

When age and sex were controlled for, 5 of the 14 Part II domains discriminated significantly between diagnoses. These were rebellious behavior, withdrawal, stereotyped behavior, psychological disturbances, and use of medication. Different diagnostic groups were characterized by different types of maladaptive behavior: violent and antisocial behavior was more predominant among neurotic and affective patients,

TABLE 1
Comparison of ABS Part I Scores of 147 Chronic Psychiatric Patients and 46 Mentally Retarded Subjects*

ABS Part I Domains	Best Possible Score	Chronic Psychiatric Patients		Mentally Retarded Subjects		Significance**
		Mean Score	SD	Mean Score	SD

N Use of medication	3.0	1.6	74.8	2.6	44.4	p<.001

*These subjects were all over age 19. The number of mentally retarded subjects tested on domain E was 63; the number tested on domain M was 121; these two groups had IQs between 68 and 83.
**The optimal score for each Part II domain is zero.
***By z test of proportions.

but chronic undifferentiated schizophrenic patients were rated worst on inner-directed domains, such as withdrawal, stereotyped behavior, and self-abuse. With the exception of domain I of Part II, organic patients showed little behavioral disturbance. The best scores on 9 Part II items were those of residual schizophrenic patients. Maladaptive behavior was most widespread among chronic undifferentiated schizophrenic patients.

Placement and Duration in Care

The social functioning of patients receiving different levels of care was ranked consistently. The most competent, stable patients were in approved community foster homes, the most unmanageable and disruptive in the hospital, and the incompetent physically infirm in nursing homes.

Performance on the ABS was correlated with length of stay in care. Significant, generally negative associations were found for almost half of the domains, although no direct inferences can be drawn from this finding alone. Patients with the lengthiest hospitalization received significantly worse ratings on all but two Part I domains as well as on withdrawal, stereotyped behavior, unacceptable and eccentric habits, and self-abusive behavior, although they had fewer psychological disturbances and received less medication. Longer community stay was associated with significantly better ratings on 7 of 10 Part I items and with a decrease in withdrawal and unacceptable and eccentric habits.

TABLE 3
Relationship Between ABS Part I and Part II by Psychiatric Diagnosis

Psychiatric Diagnosis	ABS Part I (Daily Living Skills)	ABS Part II (Interpersonal Behavior)
Schizophrenia, residual (*ICDA-8* 295.6)	Good	Good
Neurosis, personality disorder	Good	Fair/poor*
Affective disorder	Good	Fair/poor*
Organic syndrome	Poor	Good
Schizophrenia, differentiated syndrome (*ICDA-8* 295.0–5)	Fair	Fair/poor**
Schizophrenia, chronic undifferentiated (*ICDA-8* 295.9)	Poor	Poor**

*Hostile, aggressive type.
**Withdrawn, bizarre type.

DISCUSSION

The ABS indicates different patterns of social functioning and identifies patient groups with special difficulties. The chronic patients' major deficiencies spanned both parts of the ABS and were essentially those noted by Paul as critical to outcome among chronic patients' "work, social participation . . . bizarre behavior and . . . management problem(s)" (5). The patients' performance on occupational domains was very poor, the majority were seriously socially withdrawn, and, although bizarre behavior was somewhat less common, behavior likely to create severe management problems, e.g., uncooperativeness (domain C), violent, destructive, and antisocial behavior, and various puerile and demanding types of behavior (domain M), was widespread.

However, when individual groups were examined, global uniformly poor functioning was uncommon. The two parts of the ABS appear to tap quite different strengths and weaknesses: on factor analysis (6, 7), two major dimensions of social functioning were found: one, personal independence, related almost exclusively to ABS Part I; the other, social maladaptation, related to Part II. Table 3 uses diagnosis as an illustration to demonstrate that good performance on instrumental role tasks was no criterion of success with interpersonal expressive domains. Both the neurotic and affective patients and the residual schizophrenic patients were rated highly on Part I, but, although the residual patients performed equally well on Part II, the neurotic and affective patients did very badly. Conversely, organic patients displayed marked ineptitude on Part I but were virtually free of serious disturbance on Part II. Alone of the diagnostic groups, the chronic undifferentiated schizophrenic patients appeared to be socially dilapidated chronic patients with unrelieved deficits in all areas. Two main types of maladaptive behavior on Part II were discernible, the aggressive antisocial and the withdrawn-bizarre type.

CONCLUSIONS

Target areas for rehabilitation may be suggested by examining relative levels of social functioning on the two parts of the ABS and the specific areas of greatest deficit. On the basis of ABS findings in conjunction with clinical data, patients may, for example, be selected for milieu or social learning programs with limited, specific goals or placed in patient-run residences where a reasonable mixture of social skills among the deficiencies would be desirable. Extension of the use of the ABS, e.g., to long-term outpatients, would be useful in establishing the limits of social functioning of chronic psychiatric patients.

Restructuring Rehabilitation for Women: Programs for the Female Drug Addict

BY KATHLEEN M. DOYLE, MARK A. QUINONES, PH.D., M.P.H., GEORGE TRACY, M.A., DARLEEN YOUNG, AND JACQUELINE HUGHES

Two residential therapeutic communities for female addicts—one coeducational and the other all female—encountered serious problems shortly after their formation. The authors found that the male and female staff of the coeducational program had quite different perceptions of the purposes and characteristics of the women's part of the program. In both programs the female staff held such strongly ambivalent feelings toward their roles as women and authority figures that they had difficulty functioning effectively. The authors suggest the need for research that will identify the female addict's special needs, and a restructuring of programs to meet those needs. Further, training programs for female staff must enable them to distinguish between their own ideals and their clients' needs.

HOW, BY WHOM, and in what setting the rehabilitation of the female drug abuser is best accomplished is a subject of increasing concern to clinicians and researchers alike. In the early 1970s studies that focused on drug abusers and drug treatment programs generally reported only the percentage of women in treatment (20% to 25% of the total treatment population) and their retention rates, which differed little from those of their male counterparts (1–4).

Somewhat later studies explored psychological and social variables as they related to female addicts. Miller and associates (5) compared the value patterns of addicts by sex and found that female addicts tend to place a higher value on good interpersonal relationships and feelings of self-respect, while men place more value on qualities of competence and achievement. Richman and Levine (6) studied sex differences in the psychiatric backgrounds of narcotic addicts and found that significantly more women than men reported that they had had a "nervous breakdown" or had felt that one was impending. Both research groups concluded that these distinctions reflected general differences between the sexes rather than any differences specific to the drug experience. Indeed, these findings confirm those of Mellinger (7) and Suffet and Brotman (8), who reported that women use drugs for different social and psychological reasons than do men and exhibit significantly different patterns of drug abuse, more often abusing barbiturates and alcohol.

Other studies explored the types of treatment that women receive in traditional treatment programs. Levy and Doyle (9) examined both a methadone maintenance program and a therapeutic community in Newark and found that therapists regarded female clients as more deviant and "sicker" than the men and thus harder to help. The male clients regarded these women as having it easier both on the street and in treatment and thus being in less need of help. These researchers also found stereotypical treatment of women in terms of low therapeutic, vocational, and educational expectations and services. In the therapeutic community, for example, men, to attain graduation, were expected to have a job, an apartment, and a bank account; women were expected to have a man. Similar differential treatment of women has been documented in other representative drug treatment programs (10, 11).

Faced with evidence that the female addict presented different treatment problems and was apparently receiving inadequate and inferior treatment in existing programs, the National Institute on Drug Abuse (NIDA) and a few individual programs acted to correct the situation. In 1975 NIDA funded five 3-year demonstration programs for women—two methadone maintenance programs aimed at the pregnant addict, two therapeutic communities, and one outpatient drug-free program. These programs have built-in evaluation; they are now at the 3-year point and, with the exception of the methadone maintenance programs, are having great difficulty retaining staff and recruiting and keeping patients. (This material comes from conversations with researchers at the NIDA-funded women's demonstration programs.)

Recent large-scale studies have further confused the issue. Using files from the Client-Oriented Data Acqui-

Ms. Doyle is Assistant Director and Dr. Quinones is Director, Division of Drug Abuse, Department of Preventive Medicine and Community Health, New Jersey Medical School, 100 Bergen St., Newark, N.J. 07103. Dr. Quinones is also Associate Professor, Departments of Preventive Medicine and Psychiatry, and Ms. Young and Ms. Hughes are Research Assistants, Division of Drug Abuse, New Jersey Medical School. Mr. Tracy is Assistant Professor, Department of Sociology, Louisiana State University, Baton Rouge, La.

This study was supported in part by grants from the Victoria Foundation, the Lillian Babbitt Hyde Foundation, and Sandoz Pharmaceutical Company.

The authors wish to acknowledge the cooperation and assistance of Mr. David Kerr, Director of Integrity House, in allowing them complete access to his program.

sition Process, Rosenthal and associates (12) studied the treatment termination rates of a random sample of 13,258 clients and found that the sex variable had no influence on retention rates. Sells (13), in a study of posttreatment outcome in a nationwide sample of programs, found that demographic variables (of which sex was only one) accounted for only 6% of outcome variance. Quinones and associates (14) explored posttreatment outcome in 6 programs in Newark's multimodality system and found that sex had no influence on outcome (although in the case of methadone maintenance it influenced retention rates in that women remained in treatment significantly longer than men).

The current situation may be summarized as follows: two bodies of literature exist, one indicating that women do as well as men in existing programs, the other that women have needs which are not effectively met in traditional rehabilitation systems. Based on the latter premise, several programs have been initiated specifically to treat the female addict. To date, their retention rates have been low, staff turnover has been high, and posttreatment client outcome studies are far in the future. Because of these difficulties, the existence of programs directed solely at the female addict is in jeopardy.

It would clearly be useful to determine the bases of the problem that these programs are having. Toward this end, the New Jersey Medical School's Division of Drug Abuse of the Department of Preventive Medicine and Community Health has analyzed an individual therapeutic community that has made extensive changes in order to better serve the female addict. Between the fall of 1974, when this program began making changes, and October 1975, its turnover of female staff was 100% and its retention rate for female clients remained the same as it had been before changes were instituted (29% after 6 months). In April 1975 the program opened an all-female facility staffed entirely by women. Six months later it faced a leadership crisis and loss of another 100% of the female staff. The retention rate for female clients remained unchanged. Thus this program faced the same problems as the demonstration programs do, and the analysis of its difficulties can be expected to elucidate the problems that other women's treatment programs are experiencing.

BACKGROUND

Integrity House is a large residential therapeutic community in Newark, N.J., with a capacity of approximately 125 clients and a treatment philosophy based on the Synanon/Daytop model. It was founded in 1968 by the same man who directs it today. In 1974 the division of drug abuse examined attitudes toward women in the program (9). The results of this study, which showed that women received less effective treatment than men, because of both derogatory staff attitudes toward women and differences in actual services, were shared with the program's director, who resolved to change his program. By October 1974 he had hired a female "director" and several female therapists and set them to reforming the treatment received by women.

By January 1975, 10 women held important clinical and/or supervisory positions. Among the innovations they had instituted were weekly female staff meetings and, for female clients, special therapy groups, nonstereotyped vocational counseling, and a program of activities.

As the female therapists exercised more power and increased both their support of each other and their influence on clients, they also began overtly questioning the policies of the male senior staff. At the same time, male senior staff were disturbed by what they saw as lack of progress, too much talking, and too little action. While admitting their sexism, the male senior staff began to make demands that the women saw as harassment, e.g., more paperwork and more evening hours. Female staff meetings were cut back. Some of the women left, angry and frustrated. By the end of August only two of the original group of female clinicians were left, and one of them was job hunting.

Later in 1975 Integrity's male senior staff decided to try again and set about creating an all female house with an all female staff. In April 1976, 18 women (Integrity's entire female population) and 3 staff members moved into the new facility. A new director of the house, an ex-addict graduate of Daytop Village, was appointed on a probationary basis. For the next 6 months she directed treatment activities and experienced increasing difficulty in retaining patients and increasing pressure from the male senior staff to conduct a more traditional program. In October, with the client population down to 7, she resigned rather than conform to mandates from Integrity's director that would have greatly changed the women's program. A month later the program closed altogether; the remaining 4 clients were moved to the coed facility.

From this brief history it might appear that the problems facing this program resulted from the interference and/or prejudice of the male senior staff. However, since other all female programs face identical difficulties, this cannot be the sole explanation.

METHOD

After the first failure, which resulted in the loss of all but 2 female clinicians (phase 1), all staff involved in trying to effect change during that 10-month period (10 men and 10 women) were interviewed by division staff, using a structured open-ended technique. A man interviewed the male staff, including all men in positions of authority and/or influence (the executive director; the directors of research, clinical activities, and social service; the administrator; and individual facility directors). A woman interviewed the female staff, including all of the female clinicians who had worked at the program during this time (the director of the

women's program, 5 counselors, 2 intake social workers, 1 teacher, and 1 nurse). All interviews were recorded and transcribed verbatim for analysis.

Interviews were structured to elicit perceptions in 7 general areas: initial goals and expectations, the authority and status given women (or taken by them), actual changes instituted by women, success or failure of these changes, ways in which difficulties were handled, reasons for eventual dissolution of the experiment in change, and views on how the program might be reformed effectively.

In analyzing the interviews, all statements relating to these areas were extracted, classified by the subject's sex, race, age, and position in the program, and tested for differences by each variable using the Cochran Q test for related samples.

In analyzing the all female facility (phase 2), 2 female research assistants spent an average of 2½ days per week observing therapy groups, staff meetings, individual counseling, and routine daily activities at the program. Each observed interaction was carefully described in writing as to purpose, participants, emotional content, intellectual content, and outcome and was coded for later statistical analysis.

FINDINGS

Analysis of interviews through which reasons for the failure of phase 1 were sought revealed significant differences between perceptions of the male and female staff in 6 of the 7 areas (there were no differences based on staff position, race, or age in either group). The only area in which perceptions were similar was that of goals.

Four findings are most relevant to the present inquiry. The women saw authority as an emanation from the male director that should be given by him and taken back by him, while men saw it as something that an individual can take for himself or herself ($Q=30.9$, $df=7$, $p<.001$). Second, the women felt that the failure of the changes was due solely to the men's prejudice against and fear of women, especially aggressive women, while the men felt the failure was caused in part by their own failure to give the women support ($Q=30.7$, $df=8$, $p<.001$).

Third, disagreement on the efficacy of the actual treatment changes instituted by women stemmed from the women's view that their innovations (e.g., trips and fashion shows) were important and effective clinical tools and the men's view of these activities as frivolous ($Q=51.3$, $df=16$, $p<.001$). Finally, all of the men stated that the successful treatment of women can only be accomplished in a coed setting, while all of the women said that it can only be accomplished in a separate, all female program.

In brief, then, data from phase 1 analysis indicate widely differing perceptions on the parts of directors and the male and female staff of the purposes and parameters of the women's program and, at the end, mutual rancor among the groups.

Analysis of phase 2 revealed substantive ways in which this all female therapeutic community was structured differently from the coed program from which it evolved.

1. The Synanon model, based on behavior modification through rewards and punishments, including harsh encounters and physical "learning experiences" such as haircuts and wearing signs, was rejected. The staff felt that reason rather than fear could best modify female behavior.

2. The staff viewed their clients as women first and addicts second. While this sounds perfectly proper, it led to a great deal of identification of staff with clients as women, to the point where roles became confused and treatment forgotten.

3. Motherhood (all but 2 of the clients had children) was viewed as a responsibility rather than a privilege, as it had been in the coed Integrity House. Thus a woman had the opportunity of having her children visit each weekend from entry into the program onward, rather than having to earn that privilege over a 3- or 4-month period.

4. The staff directed treatment much more toward the development of skills with which to succeed in the outside world (particularly work skills) rather than stressing the development of a feeling of reliance on the "treatment family," as was the standard in the coed facility. As a result, the female clients spent a great deal more time outside the treatment facility than did their male counterparts.

5. In an effort to avoid stereotyping women, the staff did not stress the "feminine" work of cleaning and cooking. As a result, the facility was often messy and/or dirty. But, also as a result, the female clients engaged in a great deal of carpentry and renovation work in the new facility.

After 6 months of operation, this all female program was in a crisis situation; it had lost 75% of its clients, and it closed soon afterward.

DISCUSSION

Juxtaposition of data from phase 1 and 2 analyses indicates that although the outward structures of the 2 phases were quite different, the operating dynamic was similar.

Perceptual data on female clinicians in phase 1 reveal that they held such strongly ambivalent feelings toward their roles as women and as authority figures that they had difficulty functioning effectively. Again, in phase 2, the female staff appeared torn between their roles as women identifying with the troubles of another woman and as treatment agents who must remain aloof in order to be effective therapists.

Data from phase 1 reveal that the female therapists believed that anything women do together as a group is clinically not only good, but highly effective. In phase 2, there was the belief that it is a woman, not an addict

or a personality disorder or a neurosis, that is being treated and that treatment is best accomplished by "togetherness" of the female staff and female clients.

In phase 1 the women's perceptions were characterized by hostility and anger toward the male staff, who were blamed for the failure of the attempt at change. After 6 months of phase 2 the same attitudes prevailed among the female staff because their director was resigning in the face of mandates by the male director of Integrity House.

Thus in both phases the dynamic of treatment moved from an initial determination to treat the female addict in a nonstereotypical manner with special attention to her unique social and psychological needs, to an overidentification of the staff with the clients' needs, to resentment of the confusion resulting from this overidentification.

The dynamic in operation was one in which social services became confused with a social movement. Social movements are characterized by cohesiveness of members, dogmatic beliefs, and merciless, often radical thought and action against an existing system. Social services, on the other hand, are activities that are only properly provided in an atmosphere in which categorization, differentiation, and logical decision making are possible. The goal of social movements is to change an existing system, that of social services, to modify circumstances or behavior within the existing system.

Several investigators (15, 16) have urged that therapists use the women's movement as a resource in the treatment of female clients. But this is quite different from the confusion we observed in the Integrity women's program and in others around the country. The staff at these centers have been influenced by the uniqueness of their programs so much that some unconsciously and others quite consciously (17) have transformed treatment centers into causes. As a result, staff become extra sensitive to criticisms, whether from outside or within, and at the same time expect support in their battles from those clients supposedly undergoing treatment.

If those clients were actually able to become members of this cause, programs would not break down, as is the case currently. It is clear that clients are not able to do so; their presence in rehabilitation programs and their status as recent addicts presenting a myriad of psychiatric problems including low self-esteem, depression, and anomie (5, 6, 9) preclude in ability to view their identify clearly, either as individuals or group members.

In his classic work on social conflict, Coser (18) noted that outside pressure on a group can only produce internal group cohesion and thus positive progress if the group is agreed on its goals. A group composed of female staff who, unconsciously or otherwise, have become fighters for the women's movement and clients who desperately need treatment is not cohesive. Thus when pressure from male directors (as in the case of Integrity House) or from outside funding agencies impinges on such a group, it disintegrates. In the cases under consideration, this has taken the form of client dropouts, staff resignations, and questions of whether programs by women for women can ever work.

CONCLUSIONS

Despite the present discouraging situation of women's programs, we cannot conclude that they should be eliminated. The body of literature which indicates that women have special treatment needs remains. What is needed is 1) research that will not only identify the female addict's special needs but also her strengths, and 2) a restructuring of programs along objective lines designed to meet those needs while using the strengths. Finally, because the evidence is strong that services and causes do not mix, training programs for female staff must be devised to enable these women to distinguish their own ideals from their clients' needs and abilities and to keep the two separate.

Early Review of Annual Meeting Papers

In order to speed the review and publication process for annual meeting papers, the *Journal* will accept for review *final* versions of papers that are ready before the meeting. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. The version received for review must be in final form and double-spaced throughout, and it must conform to *Journal* style as described in "Information for Contributors." The paper must be clearly labeled "final version," and the number assigned to it by the Program Committee, as well as the address and phone number of the corresponding author, must appear on the title page. Authors should also submit a cover letter indicating that their manuscript is ready for review and that no major changes are anticipated. These papers will be sent out for review as soon as possible; of course, none can be published before the meeting date.

If you do not use this early submission option but do wish your paper to be considered by the *Journal*, the process will be expedited if you can bring three copies of the final version to Atlanta. However, if you feel that the paper will need revision after the meeting, *do not* submit it to the session secretary.

We hope that these changes will expedite the processing and potential publication of work that is in final form before the meeting.

1977 Anniversaries

BY GEORGE MORA, M.D.

The author recalls this year's anniversaries of events and individuals prominent in the history of medicine, psychiatry, and psychology and examines their practical and theoretical contributions.

1577

Robert Burton was born at Lindley, in Leicestershire, England. He was the fourth of nine children. His mother was described as domineering and unaffectionate toward him, and his childhood was unhappy; this might have been at the root of his depressive character and the feelings of self-depreciation that permeated his entire life. He was graduated from Christ Church in Oxford with a degree of Bachelor of Divinity in 1599 and then worked as vicar of St. Thomas', Oxford, until his death in 1640. He led a very ascetic life, but he resented the celibacy then required of academicians. Typical of his time, he showed traits of misogyny.

In 1621 Burton's *The Anatomy of Melancholy* was published under the pseudonym of Democritus Junior. In spite of its noncommittal and elusive style, the book passed through six editions during the author's life and many more after his death. Burton said of the book, "I have laid myself open (I know it) in this treatise, turned my inside outward." He confessed that he got much of his knowledge from "melancholizing." Part of the book's success was unquestionably due to the extraordinary range it covered: medicine, psychology, philosophy, history, art, theology, folklore, astrology, and much more. It served as a source for many later writers, who freely copied from it until the end of the eighteenth century.

The Anatomy of Melancholy is divided into three main parts. The first deals with the causes, symptoms, and prognosis of melancholy; the second with its cure; and the third with love melancholy and religious melancholy. According to Burton, melancholy, in contrast to sorrow, trouble, fear, grief, and passion, "is an habit, *morbus somaticus*, or *chronicus*, a chronick or continuate disease, a settled humor. So have melancholy men an inward cause, a perpetual fume [cloud] and darkness, causing fear, grief, suspicion, which they carry with them." Characteristic of this condition is excess, i.e., the exaggeration of desires and feelings that are universal to everyone. Among the symptoms of melancholy, Burton mentioned hallucinations, perversion, compulsions, suspicion, jealousy, boredom, moodiness, anger, and a tendency to self-destruction. As for love melancholy, he felt that disturbances in matters of sex were not confined to the sexual union but were extended to the whole process of objectivizing love.

In matters of etiology, Burton stated that melancholy has its origin in the black bile; however, he did not exclude the influence of the stars and the devil. Among other causes of melancholy, he suggested sickness or disturbance of the body, epilepsy, jealousy, idleness, solitude, fears, and poverty. The important cause of melancholy is thus "inward," caused by "irascible" and "concupiscible" inclinations, which in turn might be made worse by three deeper causes, heredity, lack of affection in childhood, and sexual frustration. Of the three, Burton considered heredity the most important.

As for treatment, Burton disregarded bloodletting and a good number of the other major treatments of his time (e.g., witchcraft, charms, amulets, and philters). In particular cases he considered such treatments as purgatives, mild stimulants, narcotics, tobacco, diet, travel, sports (hawking, fowling, and fishing), occupation (but not assiduous study), music, merry company, and sexual gratification helpful. Because the melancholic person is not aware of the distortions of his mind, he must use another person as an external fixed point of reference. This person should have a certain knowledge of medicine, should carry a certain authority, and should be free from passions and perturbations in his own mind. The physician's influence over the patient—the "notable secret" of the successes obtained in many cases of melancholy—is paramount, especially if the patient is genuinely interested in regaining health.

Burton was quite aware of the fact that melancholy is often a symptom of the sickness of society: "The greatest enemy of man is man . . . the knaveries, impostures, injuries, and villainies, of men no art can avoid." As a remedy for this state of affairs, he proposed that property be controlled, profits be limited, privileges be abolished, equitable wages be instituted, the poor be given free care, and slums be eliminated. The government of this ideal society should be entrusted to an educated and intelligent group of trained administrators. Moreover, only people of sound mind

Dr. Mora is Medical Director, Astor Home for Children, Rhinebeck, N.Y., and Research Associate, Department of History of Science and Medicine, Yale University, New Haven, Conn. Address reprint requests to him at 32 Slate Hill Dr., Poughkeepsie, N.Y. 12603.

and body should be allowed to marry and have children.

In essence, *The Anatomy of Melancholy* is impressive for several reasons: the carefulness and thoroughness of Burton's unprecedented survey of the literature, accompanied by an array of self-observations; his conception of the state of the human mind as a continuum from normal to abnormal; the central role he assigned to anxiety and to sexual disturbances in psychopathology; his anticipation of the unconscious theory of the mind; his compassionate and enlightened attitude toward the mentally ill; his delineation of the role of the therapist in terms close to contemporary ones; and, finally, his acknowledgment of the relationship between culture and neurosis.

In Basel three volumes by Johann Wier appeared, printed by Wier's friend Oporinus, a famous printer and humanist who in 1543 published Vesalius' *De Humani Corporis Fabrica*. Wier's volumes were *Pseudomonarchia Daemonum (The Pseudomonarchy of the Demons)*; *De Lamiis Liber (A Book About Witches)*, which also included *De Commentitiis Jejuniis (About the Feigned Fast)*; and *De Ira Morbo (On Anger as a Disease)*. By 1577 Wier had already acquired renown for his book *De Praestigiis Daemonum (On the Deceptions of Devils)*, published in 1563.

Johann Wier was born in 1515 in the town of Graeves, which is on the border between the Netherlands and Germany. He was influenced in his early years by Cornelius Agrippa, a physician and student of occult sciences. Wier studied medicine according to the Hippocratic and Galenic traditions, which divided mental symptoms roughly into phrenitis (delirium with fever), melancholia (delirium without fever), and mania (attacks of great agitation). Treatment at that time was essentially based on diet, baths, and cathartics. Mentally ill people were either kept in prisons or dungeons or left to wander on their own. Wier was graduated from the medical school of Orléans, France. For more than 30 years, from 1550 to the end of his life in 1588, he was active as personal physician to Duke William of Jülich, Cleve, and Berg.

In *De Praestigiis Daemonum*, Wier covered the topic of witchcraft from theological, psychological, medical, and legal viewpoints. He warned against the unnecessary belief in the supernatural to explain natural phenomena and bitterly condemned men who practiced occult sciences. He demolished absurd beliefs in the extraordinary powers of alleged witches and rejected the belief in the aphrodisiac effects of some magic philters. He insisted that in supposed cases of witchcraft the best thing was to ask the advice of a reputable physician and obtain a careful examination of all the people involved.

From the rich clinical material scattered throughout the volume, two points stand out clearly: the importance of affects—especially love and fear—in the pathogenesis of mental diseases and Wier's detailed description of the clinical cases of mental conditions from a refined psychopathological perspective. There are descriptions of toxic psychoses, epilepsy, senile psychoses, hysteria, delusions, full-fledged paranoia, depression, manic-depressive psychosis, schizophrenia, and collective psychopathology. In essence, this volume opened new vistas in the fields of psychopathology, psychotherapy, legal psychiatry, and pastoral psychology, which justifies the claim that Wier should be considered the first modern psychiatrist. Unfortunately, he was so far ahead of his time that the importance of his message could not be assessed properly until the recent advent of dynamic psychiatry.

1677

Baruch Spinoza died in The Hague. Spinoza was born in Amsterdam in 1632 to a wealthy Jewish family originally from Portugal. He was brought up in the strict Hebrew tradition but progressively parted from it under the influence of Latin and Renaissance traditions. He chose to live in poverty, working as a lensmaker, first near Leiden and then near The Hague. He refused academic positions in order to maintain his intellectual freedom. His main work, *Ethica Ordine Geometrico Demonstrata*, was published after his death.

Spinoza was obviously influenced by the Renaissance concept of the microcosm of man and the macrocosm of nature. He identified God with nature and has therefore been considered by some as a pantheistic metaphysician, by others as a materialist and atheist. For Spinoza, spirit and matter were the same thing viewed from two different perspectives.

It has been claimed that Spinoza anticipated many basic concepts of contemporary dynamic psychology. One of these is the assumption of a thoroughgoing psychic determinism ("For such emotions, as hate, wrath, envy, etc., considered in themselves follow from the same necessity and ability of nature as other individual things, and therefore they acknowledge certain causes through which they are understood"). Another is the idea of self-preservation ("To act absolutely according to virtue is nothing else in us than to act under the guidance of reason, to live so and to preserve one's being . . . on the basis of seeking what is useful to oneself"). Still another is the idea of libido as universal to human beings ("Pleasure and pain are desire itself, or appetite, in so far as it is increased or diminished by external causes, helped or hindered, that is they are the nature of everyone").

Spinoza also anticipated the concept of the unconscious in the affective life of man ("The human mind does not involve an adequate knowledge of the component parts of the human body; those ideas of modifications are like consequences without premises, that is . . . confused ideas"). Furthermore, he anticipated the idea of ambivalence and the belief that a better adjustment to reality can be achieved through conscious knowledge of our drives and emotions.

1777

Albrecht von Haller died in Bern, where he was born in 1708 to a distinguished family. He was an extremely precocious child, interested in all fields of knowledge. He attended the medical schools of Tübingen and Leiden, where he was greatly influenced by Hermann Boerhaave. In 1728–1729, after a trip to London and Paris, von Haller came back to Switzerland and composed the poem "The Alps," which brought him renown.

After several years of research on botany in Switzerland, von Haller was named professor of anatomy, surgery, and botany at the newly established University of Göttingen in 1736. Between 1743 and 1754 he published *Icones Anatomicae*, an important contribution to the knowledge of the vessels of the human body. In 1739–1744 he wrote *Hermanni Boerhaave Praelectiones Academica*, followed in 1747 by *Primae Lineae Physiologiae*, a basic work on physiology that was used until the end of the eighteenth century.

In the field of psychology von Haller is especially remembered for his famous lessons *De Partibus Corporis Humani Sensibilibus et Irritabilibus* (1758), in which he proposed his well-known differentiation between irritability and sensitivity. He posited that irritability is an irreducible property of the muscles due to their contractibility and elasticity; sensitivity, on the other hand, is a property present only in the living being endowed with a nervous system. Because sensations occur only in the brain, which is the seat of consciousness, sensitivity is a conscious phenomenon. This dichotomy between irritability and sensitivity caused a great deal of controversy that can be followed throughout the literature on the nervous system to the end of the eighteenth century.

1877

In Philadelphia S. Weir Mitchell's *Fat and Blood—and How To Make Them* appeared. Mitchell was born in Philadelphia in 1829 to a distinguished family. He was graduated from Jefferson Medical College at the age of 21. After further study in Paris, which included Bernard's lectures on physiology, Mitchell spent the next 10 years in Philadelphia in general medical practice; he also conducted some clinical research and experiments in toxicology during this time. In 1864, as a result of his experience as a physician during the Civil War, he coauthored *Gunshot Wounds and Other Injuries of Nerves* with G.R. Morehouse and W.K. Keen. This book has remained a classic in the field; it contains clear descriptions of atrophy, nutritional changes, alterations in joints, and, of course, motor and sensory abnormalities.

From 1879 on, Mitchell worked mainly at the Orthopaedic Hospital and Infirmary for Nervous Diseases in Philadelphia. During this period he wrote *Injuries of Nerves and Their Consequences*, a scholarly and detailed monograph dealing with such complex issues as the nutritive changes in denervated extremities, the conduction of pain, and the nature of the nerve impulse.

It was during this same period that Mitchell began to develop the concept of the rest cure for treating neurotic disorders, which were then considered primarily hysterical. In 1871 he wrote *Wear and Tear* expressing his concern for the steady increase in the incidence of nervous diseases, allegedly brought about by the rising number of jobs in the cities, by the adverse climatic conditions in the United States, and by the poor health of the American woman, exacerbated by the emphasis on female education. In 1875 he wrote *Rest in Nervous Disease: Its Use and Abuse*, in which he stated that most of the successes achieved with the rest cure were with women with hysteria, which, rather unsympathetically, he called "the nosological limbo of all unnamed female maladies."

Fat and Blood became very popular soon after its appearance in 1877. The title, recognized as unfortunate, was changed in later editions to *An Essay on the Treatment of Certain Forms of Neurasthenia and Hysteria*. The cases described in it are chiefly of young, thin, sensitive women from well-to-do families who had been treated unsuccessfully by many physicians.

The range of illnesses for which the rest cure was prescribed came to include forms of melancholia as well as hysteria. The five main components of the treatment were seclusion, diet, rest in bed, massage, and electrotherapy. Mitchell was aware of the importance of the individual relationship between patient and physician. As he put it,

> If the physician has the force of character required to secure the confidence and respect of his patients, he has also much more in his power, and should have the tact to seize the proper occasion to direct the thoughts of his patients to the lapse from duties to others, and to the selfishness which a life of invalidism is apt to bring about.

By 1881 Mitchell was the most prominent neurologist in the United States. He received honorary degrees from Harvard University, the University of Bologna, and the University of Edinburgh, and in 1891 he served as president of the Second Congress of American Physicians and Surgeons.

In his 1894 invited address at the 50th annual meeting of the American Medico-Psychological Association (now the American Psychiatric Association), Mitchell compared the limited advances achieved in psychiatry with the progress achieved in medicine and surgery and boldly criticized mental hospital administrators and staff for the lack of scientific research. He advocated an ideal mental hospital that would be architecturally well planned and staffed by plenty of well-trained nurses. The resident physicians of these hospitals should be appointed through competitive examinations and should be able to carry on psychological and neuropathological research projects. Needless to say, Mitchell's comments provoked a strong reaction in many psychiatrists.

Mitchell continued his research by publishing a collection of essays under the title *Doctor and Patient*. In 1897 his masterful *Clinical Lessons on Nervous Diseases* appeared. By that time he had also become known for his extensive literary production. Among his most popular novels were *Hugh Wynne* (1897), which sold 500,000 copies, *In War Time* (1898), *Dr. North and His Friends* (1900), *Circumstance* (1901), *Westways* (1913), and several others. He was elected president of the American Neurological Association in 1909 and continued to be professionally active until his death in 1914 at the age of 84.

Lasègue and Falret's description of folie à deux appeared in the *Annales Médico-Psychologiques*. Charles Lasègue was born in Paris in 1816. He was graduated in medicine there in 1839 and became physician to many hospitals, including the Salpétrière. His name is mostly known for the Lasègue sign in the diagnosis of sciatica. He died in 1883.

Jules-Philippe-Joseph Falret was born in Vanves in 1824. After receiving his medical degree he worked for many years at the Bicêtre (1867–1884) and then was active at the Salpétrière until 1897. He was elected president of the Société Médico-Psychologique in 1872 and of the Congrès International de Médicine Mentale in 1889. He died in 1902.

In their article on folie à deux, on the basis of solid clinical data Lasègue and Falret came to the conclusion that the contagion of insanity does not occur between two people except in very rare circumstances. It might occur when an individual with an active delusion imposes it on a passive individual in such a way that the delusion becomes their common cause. It might also occur in two people who have been very close to each other for a long period of time. A delusion might also be communicated if it has a character of probability. Lasègue and Falret stated that this variety of insanity was more common among women, that heredity can be a predisposing cause, that continuous reinforcement is necessary, that the content of the delusion often represents wishful thinking, that the main therapeutic indication is to separate the two patients, and that, in most cases, the second patient is not so deeply affected as the first.

Carl Westphal presented the classical descriptions of agoraphobia and obsession. Westphal was born in Berlin in 1833. He studied medicine at the universities of Berlin and Heidelberg. In 1858 he became assistant at the famous hospital Charité, where he was influenced by Carl Wilhelm Ideler (1795–1860) and Wilhelm Griesinger (1817–1868). Wesphal was appointed to succeed Griesinger after his death. He thus became the first professor of neuropsychiatry in a Prussian university. Westphal introduced psychiatry as a regular course of a separate specialty in medicine and established a flourishing psychiatric school. Always interested in correlating clinical with anatomical findings, he described the knee phenomenon now known as Westphal's sign. He was an extremely clear and simple lecturer, and he succeeded in isolating clinical entities that served as models for later presentations. He died in 1890.

Pliny Earle's pamphlet *The Curability of Insanity* was published in Boston by the New England Psychological Society. Pliny Earle was born in Leicester, Mass., in 1809 to a Quaker family. He was graduated in medicine from the University of Pennsylvania in 1837. He then spent two years in Europe visiting mental hospitals, notably the York Retreat in England, which was run by the Tuke family, who were Quakers, and the Bicêtre and the Salpétrière in Paris, where he met Esquirol and Leuret.

Back in the United States, Earle served for a time on the staff of the Frankford Retreat, which had been opened in 1817 as Friends' Hospital on the model of the York Retreat in England.

On October 16, 1844, Earle was one of 13 superintendents of mental asylums who gathered in Philadelphia and established the Association of Medical Superintendents of American Institutions for the Insane, which eventually became the American Psychiatric Association. He served as president of this Association in 1884–1885. Also in 1844, Earle was appointed superintendent of the Bloomingdale Asylum in New York, which had been opened in 1821 for rather wealthy patients under the leadership and guidance of Thomas Eddy, a Quaker merchant. Under Earle's vigorous leadership, many improvements were introduced in the system of care at this asylum. At that time he believed that "when the insane are placed under proper curative treatment in the early stages of the disease, from 75 to 90 per cent recover."

In 1864 Earle was appointed superintendent at the State Lunatic Asylum in Northampton, Mass., where he served for more than 20 years. When he took over the asylum, which was originally founded in 1858 for 450 pauper and incurably insane persons, it was in shambles. Earle's outstanding administrative skill, his innovative approach, and his excellent relations with laymen enabled him to introduce a vast program of work for patients within the large context of moral treatment. As a result of this the hospital became solvent.

While at Northampton Earle collected the statistical data on mental patients that resulted in the publication of *The Curability of Insanity* as a pamphlet in 1877 and as a book in 1887. In the book he took strong issue with the myth of curability. Earle's main contentions were that the word "recovered" was misused and that the words "case," "patient," and "person" were not differentially defined in most follow-up studies. In view of the fact that attacks of mental illness followed by hospitalization tended to recur more than once in a person's life, in many instances a patient was considered cured each time he or she was discharged as recovered from the hospital. Earle's findings gave a definite blow to the cult of curability of mental disorders;

they have acquired new importance in the recent controversies on the recovery rate of mental patients.

Karl Abraham was born in Bremen, Germany, to an old and well-established Jewish family. After finishing his medical studies in 1901, he worked for four years at the State Hospital at Dalldorf, near Berlin. In 1906 he was appointed psychiatrist at the famous Burghölzli Hospital in Zurich. There he was influenced to study psychoanalysis by Eugen Bleuler, then director of the hospital and an admirer of Freud, and by C.G. Jung, who was at the time very close to Freud. In November 1907 Abraham first met Freud in Vienna. A friendship developed almost immediately between the two men. In December 1907 Abraham settled in Berlin, becoming the first German physician with a private psychoanalytic practice. In 1910 he founded the Berlin Psychoanalytic Society and Institute.

Abraham's analysands included Karen Horney, Theodore Reik, Helene Deutsch, Edward Glover, James Glover, Sandor Rado, Ernst Simmel, and Melanie Klein. In 1920 Hanns Sachs joined Abraham and, with a few others, including Franz Alexander, founded the Berlin Psychoanalytic Institute. By 1913, Abraham had become a member of the inner circle called the committee of the seven rings (each member had been given a special ring by Freud), composed of Freud, Sandor Ferenczi, Ernest Jones, Hanns Sachs, Otto Rank, and Max Eitingon.

During World War I Abraham worked in a psychiatric unit on the Eastern Front. A man of great personal charm and of little ambition, he remained faithful to Freud even after some of Freud's most outstanding followers, such as Jung, Adler, and Rank, had left him. Abraham died in 1925 after a prolonged illness at the age of 48.

In spite of the brevity of his life, Abraham's contribution to psychoanalysis was outstanding. As one of the earliest psychoanalysts with a background in psychiatry, he was particularly interested in the study of psychoses and their etiology. He considered the loss of a sexual or love object central to psychotic despair. He characterized depression as ambivalence between love and hate and established three levels of development of the libido related to character formation and the different types of mental illness. These are the oral stage, the anal-sadistic stage, and the genital stage. Schizophrenia and manic-depressive psychoses were characterized by a fixation or regression to the oral stage, character disorders to the anal stage, and narcissistic neuroses to the genital stage. Abraham's views of the primal depression of infants as a precursor of later melancholia were further developed by Melanie Klein and René Spitz. Abraham's *Selected Papers* was published in English translation in 1927 (reprinted 1966), and his correspondence with Freud was published in 1966.

Ugo Cerletti was born in a small town about 80 miles from Venice. He studied in Rome and Turin and received further psychiatric training in Heidelberg, Munich, and Paris. In the first three decades of his scientific activity, Cerletti dedicated himself almost entirely to the study of the pathology of the nervous system. In 1925 he was named professor of neuropsychiatry at the newly established university at Bari. Three years later he founded the neuropsychiatric clinic at the University of Genoa, which became one of the best in Italy. In 1935 he became director of the neuropsychiatric clinic in Rome, where he remained until his retirement in 1948.

In the late 1930s Sakel's insulin shock and Meduna's pentylenetetrazol (Cardiazol) shock for the treatment of manic-depressive and schizophrenic conditions received wide recognition. Cerletti, however, was the first to attempt to use electricity to bring about unconsciousness in the patient. He divided the course of events related to his famous discovery into three periods: 1) the preparatory period, dealing with provocation of epileptic fits in dogs; 2) the actual invention of the electric shock, consisting of the extensive research on the effect of electric currents on pigs and the actual application of the first ECT (70 volts for 8.2 seconds) in 1938 to a schizophrenic patient with a machine built by his associate Lucio Bini (1908–1964); and 3) the scientific study of the mechanism of ECT, which was presented by Cerletti and his coworkers in a special 600-page issue of the *Rivista Sperimentale di Freniatria* in 1940. Unfortunately, this study passed largely unnoticed because of World War II.

Cerletti considered the electrically induced epileptic attack as consisting of two stages: the first is a discharge of the autonomic nervous system originating in the hypothalamus and brain stem; the second is a motor reaction and is far less essential to the therapeutic process. He further emphasized the innocuousness of ECT, the need to repeat the treatment in most patients, the positive results obtained—especially in cases of depressive and schizophrenic reactions—and, finally, the practical aspect of its low cost. Other studies dealt with the physiological reactions of the organism to ECT and with the amnesia resulting from it.

ECT continued to gain acceptance all over the world. It was unquestionably the most popular method of shock treatment. In recent years, however, controversies have developed concerning the use of ECT in relation to patients' legal rights and other issues.

Cerletti received wide recognition for his contribution to the treatment of mental illness. In Italy he was named president of the Italian Psychiatric Association. Outside Italy, he received honorary degress from the universities of Paris, Rio de Janeiro, São Paulo, and Montreal. In 1959 and 1961, at the invitation of the American Psychiatric Association, he attended the annual meetings in Philadelphia and Chicago; although he was over 80 years old, those who had the opportunity to meet him could not help but be impressed by his alert and inquisitive mind, by his kind and unassuming attitude, and by his gentlemanly demeanor. Cerletti died in 1963.

BRIEF COMMUNICATIONS

Lithium Treatment of Patients with Affective Illness Associated with Organic Brain Symptoms

BY LAURENS D. YOUNG, M.D., INGA TAYLOR, M.D., AND VALERIE HOLMSTROM, PH.D.

Lithium was used to treat the manic symptoms of affective disorder in three patients with associated organic brain syndromes. In all three cases neuropsychological testing permitted evaluation of the degree of dysfunction during the acute and follow-up periods of treatment. Lithium was effective in controlling the manic symptoms of all three patients, and there was no evidence that it caused further organic deterioration.

THE PURPOSE of this paper is to report in detail the lithium carbonate treatment of three adult patients with manic-depressive illness that occurred in association with organic brain dysfunction. Recent reports (1, 2) have indicated that lithium is a useful and safe treatment for the symptomatic control of hypomania and recurrent depressive symptoms in patients with definite signs of organic brain disorder and neurological disease. To our knowledge this report describes the only three cases of lithium treatment involving organic brain symptoms in which diagnoses of primary affective illness based on generally accepted criteria have been made (3). In addition, longitudinal observations of these cases allow inferences that the effect of lithium on the organic symptoms was partially independent of its effect on mania. In all three cases neuropsychological testing permitted comparison of the degree of dysfunction during the early and later periods of treatment.

At the time this work was done, the authors were all Assistant Professors, Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina, Charleston, S.C. Dr. Young is now Assistant Professor, Department of Psychiatry and Mental Health Sciences, Medical College of Wisconsin, 9191 Watertown Plank Rd., Milwaukee, Wis. 53226.

CASE REPORTS

Case 1. The patient was a 46-year-old crane operator. He had been diagnosed as manic-depressive, circular type, 3 years before the present hospitalization and placed on lithium carbonate. At that time he was functioning adequately on his job. He had a lifelong history of "bad temper" spells and heavy drinking. After 2 years of lithium therapy, with some relief of symptoms, the patient was admitted to the hospital for evaluation of headaches. The findings from brain scan, EEG, skull series, spinal tap, and CSF studies were normal. The pneumoencephalogram demonstrated a borderline shift of the septum pellucidum. The patient was diagnosed as having adult onset diabetes mellitus and hyperlipidemia of the Fredrickson type IV. Lithium therapy was continued, and clofibrate (Atromid) and appropriate diet were prescribed for the metabolic diseases.

After 1 year psychiatric referral was made because the patient had begun to complain that his "nerves were shot." His family had noted frequent angry outbursts. At work he felt that his supervisor was "out to get him." He admitted a 6-month history of diminishing ability to concentrate and of memory loss. He had confused the controls of his crane and allowed boxes to drop, causing damage. He was suspicious that others might be sabotaging his work area. Mental status examination revealed speech marked by circumstantiality and perseveration. He could not remember three words after 5 minutes. Findings from neurological examination were unremarkable except for confirmation of the mental status abnormalities described above. The findings from brain scan and EEG were normal. Neuropsychological testing was performed.

The patient's score on the full-scale Wechsler Adult Intelligence Scale (WAIS) was 72. The verbal scale score of 78 and the performance scale score of 67 showed a degree of scatter between subtests that was not quite significant. The digit symbol subtest score of 3 was definitely indicative of visual memory impairment out of proportion to the rest of the patient's testing. This finding was confirmed by the patient's score of 19 on the Graham Kendall Memory-for-Designs Test, a score that is in the critical range for organicity.

After 8 additional months of treatment, lithium was discontinued for a 2-week period on the chance that it might have contributed to the patient's dementia. After a few days his wife reported that he had begun the project of cutting down all of the trees on a large piece of land they owned. He was overzealous in his work to the point of carelessness, and he nearly severed his fingers in an accident. He also frequently drove off in his jeep in the middle of the night, saying that he "could not sleep." A second series of testing was done 2 weeks after lithium was discontinued. Lithium therapy was then reinstituted because it seemed clear that symptomatic control was necessary.

On the Memory-for-Designs Test the patient showed a nonsignificant improvement in score from 19 to 17, still in the critical range for organic dysfunction. His Wechsler Memory Scale IQ of 80 was comparable to his previous WAIS IQ of 72. His score of 6 on subtest VI reflected the weakness with visual reproduction previously noted on the digit symbol tests of the WAIS. Thus a degree of organic dysfunction, particularly in the visual memory area, had persisted over 8 months.

During the next month the patient's poor retention and recall persisted, and his family reported frequent verbal threats and occasional violent outbursts. Phenothiazines were added to his treatment regimen. After an additional 1½ years on this regimen, the patient has not deteriorated further, but he has been unable to work or return to his family for any substantial period of time.

Case 2. This 55-year-old woman, a high school teacher with a master's degree, was first hospitalized because of recent episodes of confusion, agitation, and bizarre behavior. The patient was described by friends as frequently driving her car off alone and unannounced, and picking up hitchhikers indiscriminately. The patient proclaimed that she was the Virgin Mary. She was unable to sit still for more than a few minutes. Word salad, flight of ideas, and loose associations were noted. Her affect seemed incongruously depressive. The findings from physical and neurological examinations were unremarkable.

The patient had a history of recurrent depression going back several years. She had been treated with psychoanalytic psychotherapy for 4 years, with some improvement. She had been treated somewhat successfully with phenothiazines and antidepressants for 3 years, until this hospitalization. In the past the patient had suffered from migraine headaches. She had been treated with methysergide (Sansert) for years until ascites and jaundice developed. Cirrhosis, diagnosed by open liver biopsy, was thought to be related to the methysergide, although the possibility that phenothiazines and antidepressant medication had contributed to the cirrhosis could not be excluded.

Therapy, first with haloperidol (Haldol) and then with thiothixene (Navane), was ineffective because doses high enough to remit symptoms could not be given without causing liver toxicity. The patient continued to have periods of agitation requiring seclusion and mood swings characterized by euphoria alternating with depression, irritability, and delusional religious preoccupations. She was placed on lithium carbonate, and within 5 days therapeutic blood levels were reached, with dramatic clearing of her psychotic symptoms.

With the clearing of the manic symptoms, it was noted that the patient's level of intellectual functioning was not consistent with that of a master's degree-level teacher. The patient's score on the full-scale WAIS was 117—in the bright/normal range. The degree of scatter between subtests, a verbal score of 121 and performance score of 109, was sufficient to suggest organic brain dysfunction. The patient's digit symbol subtest score of 6 was 1.93 standard deviations below her mean for all performance subtests, suggesting impairment in perceptual motor ability. Her score of 6 on the Memory-for-Designs Test was within the borderline range for organic dysfunction. Testing was repeated 2 months after her discharge to evaluate the effects of continued lithium therapy. This testing showed considerable improvement in perceptual motor ability. Her Wechsler Memory Scale IQ of 114 was consistent with her previous full-scale IQ, but her subtest VI score of 8 represented a considerable improvement in visual reproduction ability. Similarly, her score of 1 on the Memory-for-Designs Test represented enough improvement to place her in the normal range.

Later, because of her increasing frequency of headaches, the dose of lithium was decreased. When the patient became more agitated, lithium treatment was reinstituted at the original level. She was referred for biofeedback treatment of her migraine headaches and was followed for up to 1 year, with no return of the manic or depressive symptoms.

Case 3. The patient, a 71-year-old male retired civil engineer, had been scheduled for elective inguinal hernia repair. Transfer to the psychiatry service was arranged before surgery because of the patient's nervousness, agitation, and bizarre behavior. It was noted that the patient's speech rambled and that he paced about the ward in an agitated manner. He was confused about the transfer, insisting that the hospitalization was for surgery. His recent memory was impaired. The history obtained from his wife indicated that he had been hospitalized once years earlier for ECT and 3 years earlier, when he received antidepressant medications. Although in the past he had been told he was hypertensive, he was not hypertensive at this time. Physical examination revealed some weakness of the left hand, a left grasp reflex, and difficulty with tandem walking.

The patient was treated initially with chlorpromazine and brief periods of seclusion. He complained of vertigo, which the seclusion seemed to intensify. He frequently tried to unbutton his shirt, even when he was not wearing a shirt with buttons. He cried out gleefully at others, trying to touch them and their clothing. He usually had a bright and animated expression on his face. He repeated jinglelike phrases over and over again and used odd rhyming words. He began to insist that he immediately have off-ward privileges and made elaborate plans to accomplish his move.

A diagnosis of manic-depressive illness was proposed, and lithium carbonate therapy was started. Because of the patient's age the dosage was raised gradually. In a few days his rate of speech dropped markedly. He became more cooperative. By the time therapeutic serum levels were achieved, his bizarre touching and rhyming behavior had ceased. He continued to show occasional motor hyperactivity, short attention span, and lapses of memory. Although the weakness, grasp reflex, and ataxia noted on admission disappeared, neuropsychological testing and EEG were arranged as soon as the patient could cooperate.

The EEG showed bilateral slow waves over both temporal poles. Neuropsychological testing showed a full-scale WAIS score of 110. Scatter between subtests, a verbal score of 111 and performance score of 106, was not significant. The patient's digit symbol score of 6 was 1.73 standard deviations below the mean of the other performance scale subtests. His score of 10 on the Memory-for-Designs Test was in

the lower end of the borderline range for organic brain dysfunction. Together, these test scores suggested a degree of organic dysfunction during the early stages of lithium therapy.

The patient was later transferred for hernia repair. Before surgery he was taken off lithium and within a few days after the operation developed signs of confusion and hyperactivity. He described a feeling of being trapped in "the belly of a whale." He stayed up at night pacing and kept his family awake with his repetitive phrases. Lithium therapy was reinstituted. His symptoms subsided rapidly, and he was euthymic within a few days. After about 1 year of follow-up in lithium therapy, he has shown no signs of depression or mania. EEG repeated after several months of therapy showed no persistence of the slow waves. The patient was taken off lithium therapy for a 4-week period after 1 year of treatment, and neuropsychological testing was repeated.

At that time he had a score of 9 errors on the Memory-for-Designs Test, indicating an absence of signs of organic dysfunction. His score of 112 on the Wechsler Memory Scale was comparable to the previous testing, and his subtest VI score of 13 was also consistent with earlier results. The patient was taken off lithium after 6 months and, after 1 year, has needed no further treatment.

CONCLUSIONS

Although these 3 patients were similar in that they all had concurrent diagnoses of manic-depressive illness, manic type, and organic brain dysfunction, some differences in their response to treatment deserve comment. Patient 1 had a 2-year-old diagnosis of manic-depressive illness and had been treated with some success with lithium when he developed a slowly progressing insidious dementia. The relationship between the organic brain findings and the mania is unclear, but lithium appeared to ameliorate the manic symptoms and have little effect (positive or negative) on the brain dysfunction. Patient 2 had a history of recurrent depression, and her first acute manic symptoms responded to lithium dramatically. It is not clear whether lithium ameliorated the organic brain dysfunction since the symptoms cleared more slowly, but lithium clearly did not worsen the brain dysfunction.

Patient 3 appeared to develop manic symptoms and brain dysfunction concurrently. Both the mania and organic brain dysfunction cleared relatively rapidly with lithium treatment. There was some evidence in this case that lithium may have been beneficial to the symptoms of mania and to the symptoms of organic brain dysfunction, since both seemed to remit when lithium therapy was reinstituted. In spite of the individual differences, there was no evidence of progression of organic brain dysfunction attributable to lithium.

The evidence presented in these three cases indicates that lithium carbonate in the usual dosage range is effective in the treatment of hypomanic and manic symptoms when a manic-depressive illness is complicated by organic brain disorder. In this respect, our data tend to agree with previous reports (1, 2). However, in contrast to previous reports all 3 patients fulfilled the criteria for primary affective disorder (3, 4). That is, they all had illnesses of longer than 6 months' duration, with affective symptoms. It is not clear whether our group's disorders should be classified as unipolar with organic psychosis or as true bipolar affective disorder. During the period of time that these patients were maintained on lithium they were dramatically free of either manic or depressive symptoms, a response reportedly more characteristic of bipolar than unipolar patients (5).

In all 3 cases, follow-up a year or more later showed that lithium maintenance appeared to provide symptomatic relief without adversely affecting the associated organic brain syndromes. None of these patients showed any progression of organic dysfunction during follow-up. Patient 1's organic brain syndrome remained essentially stable, but lithium appeared to ameliorate his manic-depressive psychosis. Patients 2 and 3 showed improvement in affective symptoms that appeared specifically related to lithium, whereas improvement in their organic brain dysfunction occurred more slowly. There was some evidence from case 3 that lithium might even have had a beneficial effect on the patient's organic dysfunction.

Although it is usually assumed that mania appears early in life, its appearance later in life is probably not rare, and thus its association with brain syndromes may be common. On the other hand, lithium itself has been implicated in subclinical EEG abnormalities (6) and may contribute directly to organic brain syndromes (7). Although one cannot generalize on the basis of evidence from just 3 cases, our data support the safety and effectiveness of lithium for controlling manic or hypomanic symptoms without adversely affecting associated organic brain dysfunction.

The Treatment of Perceptual Disturbances in Schizophrenia with Naloxone Hydrochloride

BY ALBERT A. KURLAND, M.D., O. LEE MCCABE, PH.D., THOMAS E. HANLON, PH.D., AND DOROTHY SULLIVAN

The authors treated 12 schizophrenic patients who had overt hallucinatory symptoms with intravenously administered naloxone hydrochloride, a narcotic antagonist purported to have antihallucinatory properties. They found no evidence of the effectiveness of naloxone in preventing hallucinations over that of placebo when administered in a randomized, double-blind fashion.

THE SEARCH FOR COMPOUNDS that might alleviate the hallucinatory symptoms of schizophrenia has recently focused on naloxone hydrochloride, a narcotic antagonist used in the treatment of opiate overdose. The use of naloxone as an antihallucinatory agent is an outgrowth of the recent investigational interest in endorphins (endogenous morphinelike substances) as neurotransmitters or neuromodulators (1–4) and represents a specific attempt to test the hypothesis that endorphins might be implicated in much of the aberrant behavior associated with schizophrenia.

Supporting evidence that the endorphins may have significance beyond their obvious implications for pain perception and narcotic addiction is rapidly accumulating. The Swedish investigators Terenius and associates reported preliminary evidence of elevated endorphin levels in the spinal fluid of schizophrenic subjects (5). Bloom and associates found that certain endorphins produce anomolous behavioral effects when injected into the CSF of rats (6). In particular, they found that β-endorphin induces a state of marked and prolonged muscular rigidity resembling catatonic schizophrenia that is reversed within seconds following the injection of naloxone.

This study was supported by a grant from Endo Laboratories, Inc., a subsidiary of E.I. duPont de Nemours and Co., Garden State, N.Y. The authors wish to express special appreciation to Ms. Carol Turner and Ms. Patricia Stimely for nursing assistance; to Dr. Richard Yensen for patient selection and referral; to Ms. Edwina Wilkinson for analysis of the data; and to Ms. Hazel Bohmer for typing the manuscript.

The potential role of the opiate antagonists in the treatment of the perceptual/cognitive disturbances of schizophrenia remains to be elucidated. The rationale for the use of naloxone in counteracting the activity of endogenous opiates is predicated on the fact that because of its high stereospecific affinity for the opiate receptor sites in the CNS, naloxone displaces previously administered (exogenous) opiates from their receptor sites. The probability that such pure antagonists as naloxone and its congener, naltrexone, have relevance in the treatment of schizophreniform behavior is at least partially supported by the observation that the undesirable narcotomimetic and psychotomimetic side effects routinely observed in heroin addicts during the early (induction) phase of treatment with cyclazocine, an agonist-antagonist, are easily reversed with naloxone (7, 8). Of more direct import is the preliminary work of Gunne and associates (9), who administered intravenous naloxone to 6 hallucinating schizophrenic patients in a single-blind pilot study and observed that perceptual disturbances were attenuated or abolished for a period of several hours in 4 of the 6 patients. Moreover, the experimental treatment of all 6 patients was administered without discontinuing ongoing neuroleptic medication.

The above neurochemical evidence that the endorphins may play a significant role in the modulation of normal and abnormal human behavior, combined with reports of the regulatory role narcotic antagonists might serve in the treatment of such disorders, prompted the present pilot investigation of the effects of naloxone on the hallucinatory behavior of schizophrenic patients.

METHOD

Our study sample was composed of 12 chronic schizophrenic patients (7 men and 5 women) in whom perceptual distortions were a paramount feature of the illness. Ranging in age from 25 to 50 (mean=41.5), the subjects were patients of Spring Grove Hospital Center in Baltimore, Md. They had all manifested psychotic symptoms for at least three years. They were free of any serious physical disorders and had no recent history of alcoholism, drug addiction, or drug allergies.

The experimental treatment schedule, implemented in a double-blind randomized design, spanned two consecutive days; two intravenous preparations were

administered each day. Five of the subjects received injections of naloxone[1] on day 1 and injections of placebo on day 2; 7 received placebo injections on day 1 and naloxone injections on day 2. The determination of active drug versus placebo administration days was made by random assignment within sex; each subject served as his or her own control. For each day, the first injection was 1 cc and the second was 3 cc, administered a half-hour apart. For the active preparation, the respective dosages involved were 0.4 mg and 1.2 mg. As in the earlier work of Gunne and associates (9), the prescription of ongoing neuroleptic medication was uninterrupted during the course of experimental treatment.

A rating form was designed to assess pretreatment and posttreatment levels of hallucinatory behavior. Assessments of frequency of hallucinations were based on the personal expression or overt manifestation of distortions in the following perceptual modalities: auditory, visual, tactile, olfactory, gustatory, and somatic/kinesthetic. Our attempt to quantify changes in these modalities, although readily accomplished in some verbal and cooperative patients, had to be pursued by periodic questioning in patients who volunteered little information spontaneously. Despite this difference in responsiveness, we obtained the impression that what was subjectively reported by the patients was fairly reliable.

Before we prescribed the experimental treatment, each patient and his or her representative family member signed a form documenting that the patient's consent to participate in the study was voluntary and informed, in accordance with the basic elements of informed consent specified by the U.S. Department of Health, Education, and Welfare (10).

RESULTS

Along with summary data on selected patient characteristics, table 1 shows the presence or absence of hallucinatory symptoms of any kind before and at the end of both naloxone and placebo treatments. The lack of a differentially positive naloxone response in terms of the presence or absence of symptoms is evident. Of 8 patients who had hallucinatory symptoms before naloxone treatment, only 2 showed a complete disappearance of symptoms following subsequent naloxone injections. Correspondingly, of the 12 patients who had hallucinatory symptoms before placebo administration, 5 showed no symptoms following treatment.

Eight patients manifested hallucinatory symptoms before both naloxone and placebo administrations. The symptoms of 5 of these (patients 1, 8, 9, 11, and 12) persisted under both naloxone and placebo conditions, and those of 2 showed reductions of approximately equal magnitude in both instances. The hallucinatory symptoms of the remaining patient who had hallucinatory symptoms before both treatment conditions (patient 3) showed no change after naloxone administration but disappeared after placebo administration.

Auditory hallucinations were the most prominent of the perceptual disturbances; these were observed in 8 patients before naloxone treatment and in 9 patients before placebo administration. The mean frequency ratings for these patients were 4.1 and 4.2, respectively (4=very often). Following treatment, the respective mean frequency ratings were 3.1 and 3.0 (3=fairly often), indicating some improvement but a lack of differential drug response. Six patients who had auditory hallucinations before both naloxone and placebo treatment sessions responded in a consistent manner on the two occasions; 2 of the 6 patients responded favorably, and the remaining 4 showed no change.

Although they occurred too infrequently for definitive analysis, ratings of the hallucinatory symptoms associated with other perceptual modalities revealed no differential tendencies as far as treatment intervention was concerned. As for side effects, the use of naloxone with acutely disturbed schizophrenic patients concurrently receiving neuroleptic drug treatment (see table 1) resulted in no observable clinical complications.

DISCUSSION

The fact that we failed to confirm the hypothesized antihallucinatory effect of naloxone in this pilot study is subject to several interpretations. Either there is, in fact, no difference between the antihallucinatory effect of naloxone and placebo, or there are alternative explanations for the findings.

Although failure to corroborate the positive findings of Gunne and associates (9) appears most explicable in terms of application of more rigorous testing conditions, especially in view of the fact that in our study higher dosages of naloxone were used, the conflicting results might possibly be due to differences in the types of patients treated in the respective studies. Presumably, phenomenologically similar hallucinatory symptoms can be manifestations of several types of schizophrenic disorders, varying in etiological bases from maladaptive reactions to endogenous conditions. If patients with elevated endorphin levels constitute one segment of a study population, a differential selection of patients with respect to this dimension could lead to inconsistent findings when the treatment in question is specific to elevated endorphin levels.

Our finding that naloxone is ineffective in the treatment of the hallucinatory symptoms of schizophrenic patients underscores the complexity of the problem

[1]The drug used in the study, marketed as Narcan, was formulated in an injectable aqueous solution: each ml contained 0.4 mg of naloxone hydrochloride, 8.6 mg of sodium chloride, 2.0 mg of methylparaben and propylparaben in a ratio of 9:1, and water for injection as needed to 1.0 ml. Identical-appearing formulations except for the absence of naloxone were available for placebo administration.

TABLE 1
Selected Data on Patient Characteristics, Gross Hallucinatory Activity, and Experimental Conditions (N=12)

Patient	Sex	Age	Type of Schizophrenia	Concurrent Medication	Type of Hallucinations Under Experimental Conditions			
					Before Naloxone	After Naloxone	Before Placebo	After Placebo
1	Female	50	Chronic undifferentiated	Mesoridazine, chloral hydrate	Auditory, visual	Auditory, visual	Visual	Visual
2	Female	44	Chronic undifferentiated	Trihexyphenidyl HCl, loxapine succinate, chlorpromazine	None	Tactile	Tactile	None

Increased Sympathetic Nervous System Activity in Alcoholic Patients Treated with Disulfiram

BY C. RAYMOND LAKE, M.D., PH.D., L. FRANKLIN MAJOR, M.D., MICHAEL G. ZIEGLER, M.D., AND IRWIN J. KOPIN, M.D.

The authors measured plasma levels of norepinephrine (NE) and dopamine β-hydroxylase (DBH), pulse rates, and blood pressures of 81 hospitalized alcoholic patients. Treatment with 500 mg/day of disulfiram (but not 250 mg/day or placebo) resulted in small but significant increases in plasma NE and in blood pressure. The 500-mg dose did not appreciably inhibit DBH. Patients receiving high doses of disulfiram should have their blood pressure monitored and their dose decreased to 250 mg/day when possible.

DISULFIRAM (ANTABUSE) has been used in the treatment of alcoholism for three decades (1). The drug inhibits liver aldehyde dehydrogenase, which leads to high circulating levels of acetaldehyde when alcohol is ingested and subsequently oxidized to acetaldehyde by alcohol dehydrogenase (2). The resulting "acetaldehyde syndrome" may be related to sympathetic nervous system (SNS) discharge (3) and is characterized by vasodilation, orthostatic hypotension, tachycardia, a throbbing headache, vomiting, and, infrequently, death (4). Disulfiram alone has side effects of fatigue, tremor, reduced sexual potency, headache, and dizziness (5), and these effects can be mediated by the SNS.

Norepinephrine (NE) is the transmitter of the SNS. Dopamine β-hydroxylase (DBH), the enzyme responsible for the formation of NE from dopamine (6), contains copper ions (7) and is inhibited by disulfiram and its metabolite, diethyldithiocarbamate (8). Both compounds chelate copper ions essential to the catalytic activity of DBH. In experimental animals large doses of disulfiram inhibit DBH (9, 10) and reduce tissue levels of NE (11), but it is unlikely that the smaller doses used in patients effectively inhibit NE synthesis since DBH is present in great excess in mammals (12).

DBH is a component of NE storage vesicles and is released along with NE from the adrenal medulla (13) and sympathetic nerve endings (14, 15). The enzyme is present in human plasma (16), but its levels vary widely among individuals and provide a poor index of acute changes in sympathetic neuronal activity (17, 18). Plasma levels of NE appear to provide a more reliable biochemical index of SNS activity (19). Two prior studies investigating the effect of disulfiram on plasma NE levels used the fluorometric methods then available to estimate NE levels (20, 21). Those estimates compare poorly with more recent measures of NE levels in human plasma (19). Accordingly, we have examined SNS activity in alcoholic patients given the commonly prescribed doses of disulfiram as compared with alcoholics given placebo.

METHOD

Eighty-one alcoholic men admitted to the Alcohol Rehabilitation Unit of the National Naval Medical Center, Bethesda, Md., gave their written, informed consent for participation in the study. These patients, who drank excessive amounts of alcohol either habitually or episodically, lived in the hospital during the study and were closely monitored by one of us (L.F.M.) to exclude alcohol consumption. Patients were also excluded from the study if significant secondary medical complications or severe alcohol withdrawal symptoms supervened. The mean (±SE) age of patients included in the study was 33±1 year. After the patients had abstained from alcohol and medications for at least 4 days, sympathetic neuronal response during supine rest and to postural change was examined. Subjects were asked to remain supine and the needle of a "heparin lock" was inserted into an anticubital vein. Pulse rate was monitored by radial palpation at 5-minute intervals and blood pressure was measured by auscultation 15 minutes after venipuncture. When the patient appeared to be relaxed and had a stable pulse rate, but no sooner than 15 minutes after venipuncture, a basal 18-ml blood sample was drawn for analysis of NE and DBH. Pulse rate and blood pressure were measured and a second blood sample was obtained after each patient had stood for exactly 5 min-

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977.

utes. This technique has been shown to give an accurate and reliable evaluation of acute SNS function (19).

Fifty-four patients who fulfilled the above criteria and remained in the hospital were then arbitrarily divided into 3 groups: group 1, 19 patients who were given 500 mg/day of disulfiram orally; group 2, 16 patients who received 250 mg/day in the form of compressed tablets (Antabuse); and group 3, 19 patients who received a placebo. After 3 weeks, responses to postural change were examined again. Eight subjects from group 2 were retested after continuing to take 250 mg/day for a total of 6 weeks. The freshly drawn blood samples were immediately diluted with an anticoagulant, 10% by volume of cold acid-citrate-dextrose solution (ACD), and centrifuged at 4° C; the plasma was then stored at −70° C until it was assayed for NE by the technique of Lake and associates (19). This method employs the radioenzymatic conversion of NE to ^{3}H-epinephrine and has a sensitivity (twice blank) of about 20 pg/ml of plasma.

DBH activity was measured in these plasma samples by the radioenzymatic method of Molinoff and associates (22) using 4 μl of plasma and phenylethylamine as substrate in the presence of 3.5 μM $CuSO_4$ at pH 5.5 in a total volume of 300 μl. DBH activity is expressed in units where 1 unit is equivalent to the formation of 1 nmol of phenylethanolamine from phenylethylamine per milliliter of plasma per hour.

RESULTS

Mean plasma levels (±SE) of NE and DBH for the 81 male patients during the first 4 days after hospitalization and after the withdrawal of alcohol but before the administration of disulfiram are presented in table 1. Levels in plasma of the neurotransmitter, NE, did not differ from 106 healthy control volunteers of the same mean age.

The change in SNS activity pre- to posttreatment with disulfiram for 54 alcoholic patients is presented in table 2. After 19 patients were treated with 500 mg/day of disulfiram for 3 weeks, the plasma levels of NE were higher than those measured before drug treatment, whether subjects were reclining or standing. Both systolic and diastolic blood pressures were elevated significantly above pretreatment values (but not to hypertensive levels) in reclining patients who received the higher dose of disulfiram. There were no significant changes in levels of DBH, in heart rate, or in blood pressure while patients were standing. Hospitalization can lower blood pressure in some hypertensive patients, and the alcoholic patients given placebo tended to have decreases in pulse rate, blood pressure, and NE levels. Patients receiving 500 mg/day of disulfiram, when compared with subjects receiving placebo, had significant increases in NE levels and systolic blood pressure while lying and standing and in pulse rate while standing.

TABLE 1
SNS Activity in 81 Unmedicated Alcoholic Patients

Patient Position	NE (pg/ml)	DBH (units)*	Pulse Rate (beats/minute)	Blood Pressure (torr)
Basal	266±13	519±42	72.2±1.2	124±2 / 79±1
Standing	572±27		92.3±1.6	119±2 / 84±2

*One unit equals 1 nmol of phenylethylamine converted to phenylethanolamine per milliliter per hour.

Patients who received 250 mg/day of disulfiram had no change in plasma NE or in blood pressure after 3 or 6 weeks of drug treatment, and did not differ from those receiving placebo. The only significant change after 3 weeks in patients receiving placebo was a decrease in standing pulse rate.

The fact that the addition of $CuSO_4$ gave a 100% increase in DBH activity in the plasma of patients both on and off disulfiram indicates that the addition of the metal ion did not mask the inhibitory effects of disulfiram on DBH activity. Patients receiving disulfiram did not have altered plasma DBH activity.

DISCUSSION

Administration of either 250 or 500 mg/day of disulfiram does not appear to alter levels of plasma DBH in reclining or standing patients, and no evidence of any significant effect on DBH activity was found. This may be attributed to the relatively small doses of disulfiram used compared with the doses (400 mg/kg) used in experimental animals to inhibit DBH. The observation that patients receiving disulfiram did not have decreased DBH levels does not rule out the possibility of some inhibition of activity, because the assay for DBH activity uses a 1:75 dilution of plasma, which would dilute any disulfiram present. The significant increase in plasma NE levels after patients were treated with 500 mg/day of disulfiram indicates that the overall level of DBH enzymatic conversion of dopamine to NE in patients receiving disulfiram is not impaired.

The higher dose of disulfiram produces a significant increase in plasma levels of NE, whether compared to pretreatment levels of the same patients or to levels after 3 weeks of placebo. This may be the result of disulfiram inhibition of aldehyde dehydrogenase and subsequent accumulation of aldehydes capable of releasing NE from sympathetic neurones (23). Disulfiram also inhibits the Mg^{++}/ATP-dependent uptake of monoamines by chromaffin granules (24), which may result in increased amounts of catecholamine reaching the plasma. The disulfiram-associated increase in plasma NE was accompanied by an increase in the blood pressure of recumbent patients. Because sympa-

TABLE 2
SNS Changes from Pre- to Posttreatment with Disulfiram in 54 Alcoholic Patients

Item	Disulfiram Dose (mg)	NE (pg/ml)		DBH (% change)		Pulse Rate (beats/minute)		Blood Pressure (torr)

[e] Different from group 3 ($p<.01$, two-tailed t test).

thetic nervous system activity beyond basal output is not usually needed to maintain blood pressure in recumbency (25), increased discharge of NE in recumbent subjects should have pressor effects.

The present data extend and substantiate our earlier pilot study (26) by finding an increase in plasma levels of NE after 3 weeks of 500 mg/day of disulfiram. With significantly more subjects in the present study, both basal and standing levels of NE were elevated after 3 weeks. That DBH does not change but blood pressure increases concomitantly with the NE elevation has been brought to light in this extended study.

Although the changes in plasma NE and blood pressure were relatively minor in this group of alcoholic patients, the results suggest that large doses of disulfiram should be used with caution in hypertensive subjects, that blood pressures be monitored in normotensive subjects receiving 500 mg/day of this drug, and that the dose of disulfiram be reduced to 250 mg/day when possible.

Screening for Alcoholism Among College Students

BY ARMANDO R. FAVAZZA, M.D., M.P.H., AND BARRY CANNELL, M.D.

When the Michigan Alcoholism Screening Test (MAST) was administered to 245 students on two midwestern college campuses, 29% of the students on the small, private college campus and 19% on the large state university campus scored more than 4 points, indicating possible alcoholism. The authors hope that this study will stimulate further research on alcoholism among college students.

COLLEGE CAMPUSES traditionally are sources of willing subjects for psychological experiments. However, campuses are difficult places in which to study the prevalence of mental disorders. Administrators are frequently frightened by the potential political ramifications of such studies, e.g., a cutting of funds by legislators or donors if the rates of some illnesses are found to be high. Some faculty and students, attracted to arguments that posit mental illness to be a figment of the imagination or the creation of a medical guild conspiracy, are hostile to psychiatric research. Frequently the issue of invasion of privacy is raised. Thus the prevalence of mental disorders among college students has been more a matter of conjecture than study.

Unlike schizophrenia or neurosis, alcoholism is a relatively neutral concept. Even the most hard-nosed scientist or supposedly enlightened skeptic can usually agree, when presented with strong clinical evidence, that a person is an alcoholic. Because alcoholism can be operationally defined, e.g., the criteria of the National Council on Alcoholism, we anticipated cooperation from faculty and students in our study.

We approached several instructors on two different midwestern campuses. One was a small, private, rural liberal arts college; the other was a large state university. We explained our project: the administration of the Michigan Alcoholism Screening Test (MAST) to a sample of students. The instructors agreed, and we visited several classes to explain our project to the students and invite their cooperation. We administered the MAST to several large groups and explained each question. The information was gathered anonymously; i.e., no student signed his or her name to the material.

THE MAST

The MAST is an easy-to-administer, 25-item yes-no instrument. The questions deal with behavior and not with either quantity of alcohol consumed or hypothetical psychological constructs. A score of more than 4 indicates possible alcoholism.

The test was devised by Selzer (1) in 1971. He gave the test in Michigan to five different groups (526 persons) and validated its accuracy by examining records of medical, legal, and social agencies. The majority of those on whom the test was initially validated were middle-aged white men. In 1972 Moore (2) administered the test to 400 general psychiatric inpatients; 30% scored more than 4 points. The correlation between the attending psychiatrists' global ratings and the MAST was 78%. Favazza and Pires (3) administered the MAST to 258 young, active duty Navy enlisted men; 96.7% of those hospitalized on an alcoholism rehabilitation ward scored more than 4 points, as did 30.5% of medical inpatients, 33.2% of orthopedic

Dr. Favazza is Associate Professor of Psychiatry and Chief of Community Psychiatry and Dr. Cannell is Assistant Professor of Psychiatry, University of Missouri-Columbia School of Medicine, 803 Stadium Rd., Columbia, Mo. 65201.

inpatients, and 22.5% of hospital corpsmen. These figures closely coincide with those of the in-depth Department of Defense study which found that 31% (Army) and 22% (Navy) of all enlisted men were heavy or "binge" drinkers (4). In 1975 Selzer and associates (5) gave the MAST as a self-administered questionnaire to four different groups (501 persons) and concluded that "a self-administered MAST questionnaire has substantial reliability and validity with the scores relatively unaffected by age and the denial of socially undesirable characteristics." A recent article on the effectiveness of the MAST when it was given routinely to 252 ambulatory patients attending a medical clinic (6) reported that 42% of all patients scored in the alcoholic range, with a 10% incidence of false-negative MAST scores.

For the purpose of our study, we administered the MAST anonymously to 245 students on the two midwestern college campuses in 1976.

RESULTS

Table 1 lists the results for 169 students in an undergraduate class in child psychology on the large state university campus (campus A). The ages of the students ranged from 17 to 27 years, with a mean of 19.9 and a median of 19.

Table 2 lists the results for 76 students in undergraduate classes in psychology, urban sociology, techniques in counseling, and introduction to social research on a small, rural, private college campus (campus B). The ages of the students ranged from 18 to 35 years, with a mean of 20.6 and a median of 20.

26–30	1	0	1	1.3

DISCUSSION

In a recent National Institute on Alcohol Abuse and Alcoholism newsletter (January 30, 1976) an article appeared about a 1970–1973 study done by Jessor and Jessor at the University of Colorado. The actual study will not be released by the authors until its publication, but according to the newsletter article the authors determined that by the end of the study more than a third of male students and slightly less than a third of female students could be classified as problem drinkers. A problem drinker was defined as a person who had had at least two drinking-related problems in the previous year. The problems included frequent intoxication (five or more times), social complications such as censure from family and friends, difficulties with school work, trouble with the law, or driving after having had "a good bit" to drink.

The alleged high rate of problem drinking in the Jessors' study is roughly comparable with the rates found in our study, i.e., 29% of the student sample on the private, rural campus and 19% of the student sample on the large state university campus. Our figures cannot be validated because we did not clinically interview our subjects. It is interesting to note that on both campuses health professionals actively involved with students thought our figures either "about right" or "a little low."

Even though the MAST is a screening and not a diagnostic instrument, we decided to reassess our data. Four questions had the highest rates of response:

1. Have you ever awakened the morning after some drinking the night before and found that you could not remember a part of the evening before? (39% campus A, 47% campus B).
2. Does your spouse (or parents) ever worry or complain about your drinking? (16% campus A, 18% campus B).
3. Do you ever feel bad about your drinking? (21% campus A, 29% campus B)
4. Do you ever drink before noon? (21% campus A, 29% campus B).

We then calculated the percentages of students who would still score more than 4 points when these four questions were deleted from the questionnaire singly and in combination (see table 3).

Even with all questions deleted, the percentage of students scoring in the alcoholic range is high (9% campus A, 14% campus B). Each of the four questions contains the word "ever." On a screening instrument "ever" is more clear than "frequently" but may in-

TABLE 3
Alcoholic Scores with Popular Questions Deleted

Questions Deleted	Students Still Scoring More Than 4 Points (%)	
	Campus A	Campus B
1	12	18
1,2	12	16
1,3	11	16
1,4	11	18
1,2,3	11	14
1,3,4	11	16
1,2,3,4	9	14
2	17	26
2,3	15	26
2,4	15	20
2,3,4	12	20
3	17	28
3,4	15	24
4	17	25

flate the final scores. It should be noted, however, that questions 2, 3, and 4 count for only 1 point, and question 1 counts for only 2 points.

Of special interest is the high proportion of female college students in our sample; 70% of our sample on campus A was female, as was 50% on campus B. On campus A 15% of the females and 28% of the males scored in the alcoholic range. On campus B 13% of the females and 47% of the males scored in the alcoholic range. In almost all alcoholism studies the rate for males is higher than that for females. Ours was no exception, although the rate for females in our study was much higher than we would have predicted.

We hope that our study will stimulate further research on alcoholism among college students. The MAST is easy to administer, well accepted by subjects, and appears to be a promising instrument. Its final usefulness will depend on validation studies of multiple populations.

Informed Consent and Confidentiality: Proposed New Approaches in Illinois

BY RONALD SHLENSKY, M.D., J.D.

The author examines the basic background and definitions of the issues of consent and, more particularly, informed consent to relinquishing the privacy of mental health records. He sets these issues in the context of some of their specific inherent problems and describes possible solutions suggested by the State of Illinois Governor's Commission To Revise the Mental Health Code.

PATIENTS ARE OFTEN ASKED to relinquish their privacy with regard to their medical records. For example, a third-party payer might insist on scrutinizing a hospital record before remitting payment; a patient might be asked by his or her physician to arrange access to another doctor's records; or a health agency might require review of records to provide meaningful service.

Those of us who keep or control medical records have a statutory and civil duty to protect privacy.

Dr. Shlensky is Assistant Professor of Clinical Psychiatry, Northwestern University Medical School, Chicago, Ill. He is also a member of the State of Illinois Governor's Commission To Revise the Mental Health Code. Address reprint requests to him at 251 E. Chicago Ave., Suite 930, Chicago, Ill. 60611.

Therefore, we may not give access to these records to anyone without the patient's consent. Consent denotes a concurrence of wills (1). Thus, although every consent involves a submission, a mere submission does not necessarily involve consent. (2). Unfortunately, the current approach to our patients' privacy often results in submission rather than consent when access to medical records is sought. The reason for this injustice is that the concept of informed consent has not caught up to this area of patient services as it has to many others.

BACKGROUND

Volenti non fit injuria is a fundamental principle of the Common Law: to one who is willing no wrong is done. Thus, the very definition of a tort (civil crime) involves the absence of consent. A battery, for example, is the unpermitted touching of another. Permission or consent might be implied: an individual jostled slightly in a crowd may not ordinarily bring suit against the jostler. A patient who has consented to surgery cannot sue his or her surgeon for battery—unless the limits of the consent are exceeded.

Consent also requires some knowledge. Since 1905 the courts have increasingly focused on this matter of knowledge (3), and the concept of informed consent has thus evolved. A surgeon who operates without having explained the risks may be found negligent. At this point I would ask, If one consents to allowing access to one's medical records without having knowledge of the content of those records, is such consent informed?

PROBLEMS

The valid giving of consent requires "sufficient mentality to make an intelligent choice to do something proposed by another" (4). Thus, capacity is a consideration. The demented, the severely psychotic, the mentally retarded, and perhaps even the simply overwhelmed are at once protected and limited by the law. They cannot be informed because of their impairment; therefore, they cannot give a valid consent. The test formula generally applied is "reasonableness": minor dementia such as a mild organic brain syndrome will not operate to invalidate consent as long as there is a reasonable awareness of the issues, consequences, and risks. When a conservator has been appointed, his or her consent is required.

Conservatorship or guardianship (in Illinois the latter term is applied with regard to children), incidentally, suspends an adult's powers to create legal relations with others. Once found incompetent, an individual may not direct the disposal or use of his or her property, enter valid contracts, marry, change domiciles, or choose agents, such as doctors, lawyers, or guardian. The legally incompetent individual will probably be unable to make a valid will and may be denied the right to vote. Often some slight mental deterioration can lead to this state of affairs. Despite the severe incursions on freedom this legal process entails, it is nonadversary in character. This process is justified by its proponents as favoring family interests above those of the individual (5). Of course, once a conservator has been appointed, informed consent must be obtained from that party.

The question of how much to inform is a vexing one for physicians. On the one hand it may be negligent or at least cruel to frighten a patient away from treatment. On the other hand, if the patient develops a complication that was not specifically mentioned, there is the possibility of a malpractice suit. Further complicating this question are numerous studies demonstrating that patients informed by their doctors of potential complications recall only 10% of what they have been told (6). Again, "reasonableness" seems to be the test.

With regard to disclosure of medical records, there seems to be little reason for giving anything less than full information to the patient. However, when a physician believes that information might be harmful to a patient, the best approach would be to so inform the patient or family but to grant access if there is insistence.

Minors present special problems (7). The law has carved out protective disabilities that prevent minors from consenting to medical treatment, except under special circumstances. Illinois allows treatment for venereal disease and drug-related problems without parental consent as early as age 12 (8). We must recognize that parents and offspring might actually be adversaries. A teenager obtaining psychotherapy might have good reason to object to parental access to his or her records. According to a decision in Massachusetts, "The limits on the legal capacity of minors to act on their own behalf were not established to defeat the enforcement of their rights" (9). In some instances the courts have found that a minor approaching majority may give a valid consent if he or she fully appreciates the nature and consequences of his or her acts (10).

SOLUTIONS

With regard to mental health records, the State of Illinois is acting to resolve some of the dilemmas raised here. The Governor's Commission To Revise the Illinois Mental Health Code has drafted legislation that directly addresses the problems of confidentiality of mental health records. The proposed solutions to these problems include the following:

1. Privacy protection is afforded to a client of anyone not prohibited by law from representing himself or herself as a therapist. Currently, inconsistent distinctions are made among the various professions; in some instances there is no statutory privacy (11).
2. A person may see his or her own record. Of

course, this is already the case for mental health records in Illinois and, for all practical purposes, for health records in general.

The person must be 12 years old; up to age 18 the parents may also have access. A parent of a patient between 12 and 18 years old may not have access if the patient objects or if the therapist believes there are compelling reasons to deny parental access. In such a case, parents may petition a court for access.

If a patient disputes information in the record, a written statement by the patient may be entered into the record. The patient may request that any part of the record believed to be misleading or incorrect be modified; a court may compel such modification if justified.

3. No disclosure of the record to others may be made in the absence of informed consent.

This consent may be given by any person 18 years old or older, by the parent or guardian of a person under age 12, and by both the patient and parent or guardian of patients between ages 12 and 18. If a therapist believes disclosure of the record of a person between 12 and 18 years old is in the person's best interest and the parent or guardian consents, disclosure may proceed in the absence of the person's consent.

The consent must be in writing and specific as to who receives the information, the purpose of the disclosure, the nature of the information, and the consequences of refusal to consent. Blanket consents and redisclosures are prohibited. Provision is made for limited disclosure without consent when it is impossible to obtain consent due to incapacity and necessary to obtain it to receive benefits.

A therapist may disclose information in the absence of consent for purposes of supervision, record keeping, peer review, and to an attorney consulted regarding legal rights and duties owed the patient.

In any civil, criminal, administrative, or legislative proceeding, a patient may invoke privilege and refuse or prevent disclosure of records or communications except in the following instances: 1) when the patient introduces his or her mental condition as an issue, 2) when the mental examination has been ordered by the court, 3) in a proceeding brought by the patient against the therapist, 4) if the therapist determines that involuntary hospitalization is necessary to prevent physical harm, 5) when facilitation of guardianship is necessary, 6) when the communications were made in the course of treatment ordered to render the patient fit to stand trial and only with respect to that issue, and 7) when required by the Abused and Neglected Child Reporting Act.

In addition, nothing in the proposed legislation may preclude a therapist from making such limited disclosure as he or she deems essential to prevent imminent, serious physical harm. Caveat: one must have capacity to validly consent.

Essentially, the drafters of this proposed legislation felt that one's record is an extension of one's self and thus deserves protection and consideration. No doubt, the conveyance of private facts to others can exercise a profound influence on the person exposed. It should be noted that Illinois will probably also have a more sophisticated approach to the problem of conservatorship. A plan is under way to implement an approach based on partial incompetency, with limits on the loss of freedoms.

CONCLUSIONS

As individual rights receive more attention, privacy deserves greater protection. To give privacy up is a serious matter. An individual must know full well what he or she is doing when he or she acts. Both common and statutory laws support this trend.

On Teaching Psychotherapy in a Community Mental Health Center

BY JEFFREY D. NASON, M.D.

The author discusses some of the unique problems related to teaching psychotherapy in a community mental health center. These problems arise principally from the diversity of philosophies and backgrounds of the health center staff and the lack of an overriding institutional tradition of psychotherapy. They often result in increased anxiety among trainees and require special attention from the teacher of psychotherapy in this setting.

THE CURRENT PROLIFERATION of community mental health centers and their increasing integration into mental health training programs brings into focus some difficult and intriguing problems in the teaching of psychotherapy. There are obvious administrative problems involved in the integration of community mental health center staff and trainees and in the balancing of responsibilities for service and training; these will not be the concern of this paper. What I wish to consider are some of the theoretical and practical problems that arise from trying to teach psychotherapy in the special circumstances of the contemporary community mental health center.

THE PROBLEM OF DIVERSITY

Psychotherapy has evolved rapidly and tumultuously in both concept and practice. We are all aware of the profound chaos and confusion of contemporary psychotherapeutic thought. Leston Havens brilliantly outlined the development of the major psychiatric schools in this century (1). In tracing the flow of changing psychotherapeutic assumptions, he showed how each assumption has become the basis of a qualitative change in psychotherapeutic practice. As Havens asserted, these changes are often unacknowledged, so that what we do becomes increasingly remote from what we say we do. Psychoanalysts practice existential therapy while talking hydraulic theory, and Sullivanians (and perhaps all of us) unconsciously become experts at behavior modification. Not only are these diverse assumptions unacknowledged, Havens argued, but they are often not understood, so that thoughtful students are confused and others become mindlessly eclectic or religiously sectarian. This situation recalls Yeats' fear that "The best lack all conviction, while the worst/Are full of passionate intensity" (2).

Granting that there are profound theoretical confusions in all of our schools, academies, and institutes of training in psychotherapy, we must still consider the special problems that have come with the emergence of the community mental health center as a locus of training. The working staff of the community mental health center—the team (including trainees)—tends to be at once both smaller and therefore more tightly integrated and substantially more heterogeneous in background, training, and therapeutic philosophy than the staff in larger, more traditional training institutions. In the traditional teaching hospital or private clinic, trainees and staff can be selected according to how they fit into the spirit or style of the particular institution. The resulting mutual intellectual support and validation, the pressures toward orthodoxy, or the presence of inspirational teachers can protect and nourish an institutional tradition involving a particular approach to psychotherapy.

The community mental health center, according to my experience, tends to attract a diverse group of therapists and would-be therapists from all parts of the intellectual, temperamental, and philosophical spectrum. There has been a substantial and, in terms of the acquisition of psychotherapeutic skills, often very useful blurring of professional disciplinary roles, but I do not think that this is the major cause of the kind of diversity with which I am concerned here. I think that the pressures on the community mental health center to prove itself, to justify budgetary allotments by demonstrating that its service, namely psychotherapy, really works, have created a climate that has encouraged diversity by fostering a pragmatic approach to symptom distress. The motto might be, "If it works, do it," rather than the more traditional, "We do it because it's the right way." As fruitful as such diversity and pragmatism have been, however, the price that is paid is often the loss of a traditional and institutional consensus on the "right" approach to a particular clinical problem. The need for clinical judgment and the chance of creative solutions are perhaps greatest in this situation, but it is also an anxiety-provoking situation for the trainee and the experienced clinician alike.

Dr. Nason is Director of Clinical Services, Brookline Mental Health Clinic, 43 Garrison Rd., Brookline, Mass. 02146, Clinical Instructor in Psychiatry, Harvard Medical School, and Assistant Clinical Professor of Psychiatry, Tufts University School of Medicine, Boston, Mass.

Unfortunately, as a result of this anxiety therapists sometimes become paradoxically more rigid, positions become fixed, and diversity becomes factionalism rather than encouraging open-mindedness.

COMPETING CLINICAL OPTIONS

One of the most exciting developments of the last 20 years has been the burgeoning of interest in family therapy. This area provides an example of the competing clinical options evident in the community mental health center. Because of the new perspective of family therapy, traditional approaches to common problems must be rethought. For example, play therapy for the child and a "child guidance" approach for his or her parents (usually the mother) when a child is symptomatic or troublesome to others or individual therapy for an adult whose problems have to do with difficulty in separating from his or her original family or in living with his or her current one have been standard approaches. These must now vie for acceptance with the newer modes of family therapy.

This new perspective can and often does add a dimension to our clinical vision that allows us to choose our therapeutic approach more thoughtfully. However, the conceptual framework for much current family therapy is quite different from that of psychoanalytically or psychodynamically derived individual therapeutic models. The concept of an interactional system and the necessity of placing individual symptoms and psychopathology within a supra-individual matrix of regulation and meaning are essentially new ideas. They can be extremely useful if they help us view our patients more holistically and if they provide another option for therapeutic approach. However, as a competing therapy, often based on very different assumptions as to what is wrong as well as how to make things right, family therapy can add to the already abundant uncertainties and anxiety of the experienced clinician and, more particularly, of the trainee.

A common clinical vignette may illustrate this point. A young woman in her 20s and working comes to the clinic complaining of depression or discouragement because she has been unsuccessful in two attempts to leave home. Each time, after taking an apartment with some friends, she has become acutely anxious and has quickly returned home to a mother to whom she has a close but chronically hostile attachment, an alcoholic father, and a younger brother who has had intermittent psychotic episodes requiring hospitalization. The family therapist, with undeniable justification, says, "It's a family problem. They cannot separate from one another. Have them all come in and we will work with them together." The individual therapist says, "But she's an adult and her problems are internalized. We should work with her alone to help her to resolve her conflicts and go on with her life. Bringing in her family might just make things worse."

To examine the clinical considerations in this question is not the intent of this paper, but I think the example evokes a sense of what the trainee must feel when confronted with such profound differences in clinical judgment and in assumptions about the nature of what is therapeutic among his or her teachers. Because the community mental health center, unlike the traditional training institution, usually has no unifying tradition of psychotherapy, the trainee often feels buffeted by the rapidly shifting winds of therapeutic fashion. On the other hand, trainees might become disciples of a charismatic teacher or one available by the accident of proximity.

THE CLIMATE OF OPENNESS

The many problems of teaching psychotherapy in the situation outlined above are obvious. One task of enormous importance is to help the student remain a student and not become a disciple. To help students develop their own vision of human nature and of the experience of psychotherapeutic change means to a large extent sharing our vision, complete with distortions and biases, with them—to let them see through our eyes. This must be done in a way that leaves them free to be open to their own experience, to view all theory thoughtfully and critically, and to learn from others who see things very differently from the way we do. These problems, which are universal in teaching, are particularly acute in the community mental health center because of the special anxiety the trainee often feels from the lack of a unifying philosophy of what is to be his or her life's work. Here the task of the teacher is to help the trainee tolerate these anxieties without premature closure of emotional and intellectual growth.

Karl Mannheim, in his appeal for a "sociology of knowledge" (3), asked that we attend to the social and institutional climate that permits or inhibits certain kinds of human awareness and understanding—that allows us some perceptions of human experience and denies us others. The community mental health center, itself a product of rapid social and institutional change, presents special problems in maintaining the quality of that climate.

SPECIAL PROBLEMS OF TEACHING

As clinical director of a community mental health clinic with an active multidisciplinary training program and a highly capable but relatively heterogeneous staff, I have found three problems of teaching to be particularly vexing and challenging. The first is that of language. We are a veritable tower of Babel. The staff talk many different conceptual languages; the task of the teacher is often to translate these. There are currently several different systematized languages in psychotherapy, ranging from psychoanalytic theory to behavior modification theory to the various family the-

ories. In many ways the biggest problem results from the hybridization (or bastardization) of theoretical terminology: we sometimes use the same words and phrases but do not always mean the same things by them. For example, it has lately become very fashionable for therapists of all schools to talk about a loss of ego boundaries. This phrase may communicate very different things to a psychoanalytic therapist, an interactionally oriented therapist, and a structural family therapist.

Obviously an attempt to minimize the use of jargon is in order, but I do not believe that all jargon can be eliminated without a concomitant loss of the sophistication of certain ideas and observations. There is often no better way to say something than the way we are used to saying it, and I think it is preferable to let people talk in their own way if they exert the intellectual discipline to be terminologically consistent and to help others understand what they have said.

The second problem is that of clinical evaluation. With staff and students from so many different backgrounds and orientations, it is perhaps not simplistic to ask what an evaluation is or why it is necessary. Listening to evaluations presented by workers with different orientations brings these questions to mind, and one must also ask what, if anything, these evaluations have in common. To refer again to the example of the young woman unable to leave her home, the family-oriented therapist might elaborate for us, in diagrammatic form, the assigned roles, alliances and boundaries, and power relationships within the family that have kept the patient in place. The psychoanalytically oriented therapist will be dissatisfied with such an evaluation because it does not tell us enough about the conflicts raging within the patient and particularly because it tells us so little of the developmental aspects of the patient's conflicts and of her resultant ego strengths and deficits. The empathically oriented, perhaps existential therapist will be dissatisfied with this account because it does not give us a sufficient sense of the patient's felt experience and the nature of her pain. Finally, the medically oriented therapist will be concerned that insufficient attention has been paid to the family history of mental illness and to the patient's current mental status to enable us to decide about diagnosis, prognosis, or the preferred mode of treatment.

Should we try to standardize a process so subtle and so complex as a clinical evaluation? Granting the creativity inherent in the individual viewpoints of different clinicians, are there not some things that we would want to know about everyone who is seen at our clinic? With these questions in mind I constructed an outline for clinical evaluations intended primarily to call attention to some of the critical areas that should be considered in every evaluation, regardless of the orientation or principal interest of the evaluator. The language selected was deliberately simple and nontechnical. It was structured around four questions: 1) Why is the patient here now? (assessment of the current situation and not just the chief complaint), 2) Who is the patient? (including relevant history and descriptive mental status), 3) How do we understand the patient and his or her current problem? (a conceptual question inviting divergent conceptual styles), and 4) What can we do for the patient? (a treatment plan). I think that these questions, which can be greatly elaborated and obviously must be modified for evaluations of families, point to simple but universally relevant things that we need to try to learn about new patients.

Finally, the most subtle and difficult area of teaching in a community mental health center involves the introduction of the trainee to the experience of psychotherapy itself. Here I must reveal my own assumption that the process of psychotherapy is primarily an affective experience involving two or more people. It is my assumption that the process of becoming a psychotherapist involves a growing knowledge and tolerance of one's own most painful feelings and a growing ability to make active and accurate empathic contact with the inner life of another. Teaching psychotherapy must therefore be largely by example, and I believe that a good deal of our success rests on the relationship between the supervisor and the trainee. I do not mean that we are to be therapists for our trainees but that empathic and sensitive attention to the experience of the trainee in learning to become a therapist in this particular time and place is essential to the success of our work.

CONCLUSIONS

The community mental health center, which grew out of the need for a greater and more equitable distribution of mental health care, has increasingly become a locus of training in psychotherapy. Because of the diversity and heterogeneity of its staff and its lack of an institutional tradition of psychotherapy, the normal anxiety of trainees learning to become psychotherapists is often greatly increased, presenting special problems for the teaching of psychotherapy. It is in this setting that much of the growth of young therapists as well as the future course of psychotherapeutic theory and practice may well be determined.

Mental Health Consultation in a Law School Clinic

BY ROY B. LACOURSIERE, M.D.

The author describes mental health consultation with legal interns in a law school legal clinic. Unique characteristics of this setting are described, including that it is not primarily a mental health area and that the consultees are trainees. Various types of consultee-centered consultation and direct and indirect client-centered consultation are discussed, as are problems that must be avoided, e.g., an excessive psychological focus on the part of the consultant or consultee.

IN THE lively community mental health movement, consultation is a basic and mandated activity. We have learned a considerable amount about the application of consultation skills with such groups as teachers, public health nurses, psychiatric paraprofessionals, and police officers. This paper describes consultation to legal interns and some of the unique aspects of this work.

Mental health consultants working with legal interns, as herein described, function primarily by helping the interns learn how to better represent their clients rather than by teaching them to enhance the clients' mental health. Good legal representation can make a significant contribution to a client's mental health—for example, when an attorney functioning as a child's guardian *ad litem* does what is best for the child rather than what might be most legally expedient or lucrative. A client who is under the stress of legal difficulties can be helped by being carefully listened and attended to. Although this is not the typical use of mental health consultation, it falls within its broad definition (1).

DESCRIPTION OF THE PROGRAM

As part of the Washburn University of Topeka School of Law's clinical legal education program, two elective semesters are offered in the in-house law office, the Washburn Legal Clinic. Students can take one semester in the junior year as law clerks and a second semester in the senior year as legal interns. The clients are represented by the legal interns, with the assistance of law clerks, all under faculty-attorney supervision. The clinic staff represents about 1,400 indigent clients each year in cases that include driving while intoxicated, divorce, child custody, commitment for treatment of mental illness or alcoholism, juvenile delinquency, and misdemeanor proceedings.

There are several requirements for a mental health consultant in such a clinic. Adequate skill in consultation is the first. Familiarity with local mental health, medical, and legal facilities is necessary to understand various aspects of the cases and to help in appropriate referrals for treatment, evaluation, etc. (The consultants also work in other settings with patients who could qualify as legal clients for the clinic on both financial and legal grounds; and patient-clients are shared occasionally.) Also required is an ability to understand and appreciate the orientation of attorneys, which stresses advocacy and legal rights. This understanding can be facilitated by reading, taking law school courses, doing forensic and civil commitment evaluations, etc. Furthermore, the consultant needs to be comfortable in his or her own profession. For example, one's professional allegiance is challenged when colleagues are on the opposing side of legal cases, as in child abuse cases in which the child has been seen by a fellow mental health professional and the alleged abusive parent is the legal clinic's client.

There are other characteristics of this consultation work that are related to the fact that consultees are not yet skilled in their own field. Although this makes them more unsure about their own roles as attorneys and in some ways hesitant to reveal their uncertainty to a consultant, their clearly defined learning role as interns can also make them more amenable to new input. Also, there are some cases in which a law or legal procedure may be more familiar to the consultant than to the intern, particularly those related to mental illness. Such bits of legal information can be conveyed unassumingly by saying something like "Let's look at the statute to be sure."

The Consultations

For purposes of presentation, the various types of consultation in the legal clinic can be arranged to follow Caplan's format (2, 3), with recognition that some of the consultation is "medical" as opposed to "mental health." Consultation methods are eloquently dis-

Dr. Lacoursiere is Visiting Assistant Professor, School of Law, Washburn University of Topeka, Topeka, Kan. 66621. He is also on the faculty of the Menninger School of Psychiatry and is Chief, Chemical Problems Treatment Unit, Veterans Administration Hospital, Topeka, Kan.

The author thanks the law school faculty, Dean Raymond Spring, Prof. Donald Rowland (Clinical Director), and Prof. Donald Frey for their help and encouragement, and the Council on Legal Education for Professional Responsibility, New York, N.Y., which partially funded the mental health consultants (Drs. Frey and Lacoursiere).

cussed in Caplan's work (2, 3) and in briefer format elsewhere (4). Consultation requires, among other things, listening at several levels to the verbal and nonverbal messages of the consultee and responding to the appropriate level or levels. The consultations themselves are usually short and "one-shot," but occasionally they have been fairly long and have extended over a few contacts. The important point in this regard is adaptation to the case and consultee as required. An attempt is made to follow the cases with the interns after the initial consultation. This allows for consolidation of the consultation and a check on its usefulness.

The most frequent type of consultation has been consultee-centered case consultation, in which the consultant meets with the intern and occasionally also the supervisor, but not with the client. The main purpose of such consultation is to help the consultees improve their functioning as attorneys-to-be and only indirectly to help the client. In spite of this, the main consultation work is done by inquiries and listening directed toward the client but always with the thought of how to help the intern with the difficulties he or she is having with the client. There is some arbitrariness in determining the subtypes of this category, one of which results from lack of understanding on the part of the consultee; e.g., difficulty in understanding the significance of certain behaviors he or she has observed. An example that is seen often is the initial angry client who wants a divorce but is slow to follow through or misses appointments as the intern prepares the case. Interns may need some help to see that in such a case a divorce may no longer be desired and that marriage counseling might be suggested.

Another subtype involves the need for consultation because of the consultee's lack of technical skill or knowledge. Once the interns have determined that psychiatric evaluation or treatment would be beneficial for the client and/or the cases, they may need assistance in deciding how and where to refer the client.

Some consultations come about because of the intern's lack of self-confidence. In such cases the intern has sufficient understanding and skill but is hesitant, often because of inexperience, to do what he or she sees as necessary. For example, the intern may lack the self-confidence to confront or ask for an explanation from a client who gives information that is inconsistent with what has been found from other sources, such as court records of previous convictions, or to recommend help for a client charged for the third time with driving while intoxicated.

In some cases the consultation focuses on the intern's lack of objectivity in the case, which may result from excessive "personal involvement" or irrational bias toward certain types of people or behavior. Technically, this is theme interference, wherein a personal bias or theme interferes with the application of one's skills, e.g., "Clients wouldn't ignore your advice if they had to pay," or "These kinds of blacks are always in trouble." This is probably the most difficult type of consultation. Such lack of objectivity may be unconscious, or if there is some awareness of a bias toward that particular aspect of the case, the intern sees it as "reasonable." In the mental health field, consultation on such cases may take a few 30- or 45-minute sessions; however, they can sometimes be done in shorter clinic sessions with only one or two meetings (5), and the law school clinic setting often makes this mandatory. In dealing with theme interference, the intern's lack of objectivity or bias is rarely confronted directly, since confrontation would usually merely make him or her defensive. Rather, the client is focused on in such a way as to try to bring about basic changes in the orientation of the intern, e.g., by asking what this black client was doing before the current legal difficulties, how other members of his family are functioning, and perhaps questions about the previous defense if there were earlier legal difficulties.

In some consultations the main focus is on the client and various aspects of the case; helping the consultee develop as an attorney is a secondary focus. Such consultations are called client-centered, and can be either indirect or direct. In indirect client-centered consultations various aspects of the case file are reviewed and discussed with the intern. Occasionally such consultations involve medical rather than mental health concerns; e.g., are certain medical reports adequate grounds for a Social Security disability claim?

In a very few cases, the client is seen with the intern (direct client-centered consultation) after the case file has been reviewed. This is particularly likely when psychological reports or recommendations have seemed inadequate or contrary to the intern's expectations or the intern needs help to decide if and where a particular client should be referred for psychiatric evaluation or treatment or what other course should be pursued. There have been several requests to see clients with whom interns said they had trouble communicating. Usually, with encouragement to help their lack of self-confidence, the interns can manage these situations quite well, and it is rarely necessary for the consultant to see the client.

The client contacts are not included in formal reports to be used in the case. The consultant is not in a position to submit neutral reports because he is an employee of the law school clinic. When such reports are required, they are obtained from the usual mental health or medical practitioners in the community. Also, having the consultant see clients directly can undercut the more difficult and more useful task of using consultation as much as possible to promote the professional development of the intern. The more the consultant performs tasks that the intern can and usually must learn to do, the less the intern's professional growth is encouraged.

The consultants are also involved at times in various discussions not covered by the above categories, both with the clinic administrative and supervising attorneys and with interns. Such discussions have covered many areas, including the morale of the intern

group and the mixed acceptance of the clinic program by some of the nonclinical law faculty and students. Although these miscellaneous areas are a small part of our consultation work, they can be technically described as program-centered administrative consultation and consultee-centered administrative consultation (2).

DISCUSSION

Mental health consultation in the legal clinic does not aim to help the consultant do mental health work with legal clients through the interns, nor does it turn the interns into mental health counselors. In fact, there are certain conflicts between an intern's "counselor" and "advocacy" roles, particularly in civil commitment procedures. There seem to be some interns who function as counselors (therapists) and others as advocates, sometimes almost in spite of their client's best interests. Some of these advocates may be hesitant to consult on cases with strong psychological components for fear of losing a client or case to the mental health (counseling) field (e.g., a divorce case to a marriage counselor). A third group of interns can more comfortably and appropriately shift between the counselor and advocacy roles as the client and case demand.

The consultant particularly needs to watch the mental health/legal boundaries when the clients have glaring and distressing psychiatric problems. For the consultant in such cases (e.g., disturbed juveniles or individuals involved in civil commitment procedures) to focus excessively on the psychopathology or let the intern do so often distracts both of them from handling the legal problem at hand in an optimum way. Under such circumstances the intern may be most helpful with the client's psychiatric difficulties by delving no further than to ask the client whether he or she is getting help for the emotional problems. Of course, there are times when psychiatric problems and the quality of psychiatric treatment are of central importance and need careful scrutiny by the intern and consultant. One such case led to litigation, which was eventually dropped, against a mental hospital and at least two of its psychiatrists. About a third of the cases for which consultation is sought are subsequently referred for psychiatric evaluation or treatment. Many of these are juvenile or child custody cases in which psychiatric evaluation or treatment is often desired by the court or intern for optimum resolution of the legal situation.

I have been favorably impressed with the quality of representation by most of the legal interns; mental patients seem to receive equal or better advocacy from legal interns compared with private attorneys. Perhaps reciprocally, the consultants have been fairly well received by the interns and the clinic faculty; about three-fourths of the interns avail themselves of consultation services. Questionnaires the interns complete to evaluate their experience in the clinic generally indicate that the consultations have been considered quite helpful.

Voodoo in Africa and the United States

BY KENNETH M. GOLDEN, M.S.W.

The author states that the practice of hexing is not just a nearly extinct phenomenon of isolated rural communities of the deep south of the United States but is evident in large urban areas in the northeast and west. He describes the psychological mechanisms of voodoo as practiced in West Africa to provide insight into similar practices in the United States.

THERE HAVE BEEN scattered reports of suspected illness and death resulting from voodoo practices in the United States (1–4). The following case is illustrative:

Case 1. A 33-year-old black man from a rural area near Little Rock, Ark., was admitted to the neurology service of the University of Arkansas for Medical Sciences. The patient had been having seizures recently and had become increasingly irritable and withdrawn from his family. When he could no longer be detained safely on the neurology service, he was transferred to the psychiatric ward, where he became increasingly more agitated, confused, and almost delirious. He became very fearful whenever people approached him, and he began to hallucinate. He finally slowed down after being given 1000 mg of chlorpromazine (Thorazine), but the necessity for bed restraint remained. All neurological findings, including a brain scan, proved normal.

After two weeks of hospitalization the patient suffered a cardiac arrest. All efforts to revive him failed. An autopsy provided no reason for the death. After he died, the patient's wife told staff members that her husband had been seeing a "two-headed," an older woman considered by the community to be a witch who cast spells and healed people. The widow stated that her husband had angered the two-headed and that she had caused his death.

"Conjure doctors," "the two-headed," "root doctors," and "hoodoo men" are believed to be able to trick or hex a person, causing sickness, insanity, and death; they are also held to be able to cure a person who has been hexed (5–7). These agents use herbs, roots, stones, powders, insects, charms, and incantations. I have heard reports of a woman who lives in a federally funded housing project in North Little Rock, Ark., who is widely regarded as capable of casting spells that can cause marital discord, illness, sterility, madness, and even death. She has a collection of voodoo literature, sets of voodoo images, and quantities of potions in her apartment.

Hexing practices are no longer a phenomenon only of rural isolated communities in the deep south. Physicians have provided evidence that voodoo and hexing practices exist as far north as Connecticut (2–4). Complex systems of voodoo practice have also been described in heavily populated urban areas (8). Similar belief systems have been shown to exist among many subcultures and ethnic groups throughout the United States, such as in the Mexican-American communities in the southwest (9–11).

Voodoo and similar cult practices are still in evidence in some areas of Africa. The practice of voodoo in the United States is a blend of African voodoo and European witchcraft beliefs. The practices that evolved in the United States were in reaction to the environment here (12). Although voodoo in the United States differs from the African practice, an understanding of the function, importance, and evolution of voodoo in its original environment may provide insight into its use and capabilities in the United States.

AFRICAN CURSE DEATH

As a Peace Corps volunteer teacher I spent two years in West Africa. There I lived in an area where the voodoo cult originated (7) and where cursing and hexing were actively practiced (13). *Vodu* in the Ewe dialect of the West African village I lived in means "one to be feared." The vodu cult was only one of a number of similarly powerful cults. (The practice of vodu was transported by Ewe slaves to Haiti and Louisiana during the early part of the eighteenth century. The primary diety of the vodu cult, the legba, appeared throughout my West African village in the form of moon-faced idols made of sun-hardened clay. The legba is still a prominent diety in Haiti.)

The village is only 8° away from the equator; the villagers barely eke a subsistence out of this scorching, barren plains area. Although the village appears to be sleepy, the lives of the villagers are strictly dictated and controlled from birth to death by the traditions of the cults. Disobedience of tribal custom is punished by fines, disgrace, banishment, or, when the infraction is particularly serious, by curse death, which means certain death to the victim.

Mr. Golden is Instructor and Psychiatric Social Worker, Department of Psychiatry, University of Arkansas for Medical Sciences, 4301 W. Markham, Little Rock, Ark. 72201.

The author wishes to express his appreciation to Dr. William Reese, Chairman, Department of Psychiatry, University of Arkansas for Medical Sciences, for his assistance with this article.

My landlady was fatally affected by such a curse. She was a prosperous marketwoman in her mid 30s who often traveled to neighboring Togo and through the southeast corner of Ghana to market her goods. For a year or so she had been suffering from severe and acute attacks of abdominal pains. She had had exploratory surgery performed by European doctors on three occasions with no positive result. Toward the end of my Peace Corps tour I noticed that she was losing weight and saw her less and less often in the marketplace. When she died, there was, uncharacteristically, no funeral celebration for her; she was buried on the outskirts of the cemetery. When I asked a friend of mine why, I was told that she had been cursed by the yehwe, one of the major cults in the village, because she had been an adulteress.

For the curse to be successful, the victim has to be made aware that he or she has been cursed. Priests learn through divination ceremonies that gods or ancestors are angered due to the transgressions of a certain villager. It is not hard to imagine how in a small village the priests could obtain this knowledge in less than otherworldly ways. The priest's divination soon becomes common knowledge. The slightest suggestion is sufficient to cause tremendous fear in the victim. Tribal laws are rigid, and all members know them. The transgressor knows that there is nothing he or she can do to reverse or negate the curse. Death comes slowly but surely over a period of months.

When the curse becomes known, the victim's family and friends as well as the entire community withdraw their support. The victim becomes an outsider to the few cohesive and organized activities of the village. He or she is thus no longer protected from the evil wishes of ancestors and witches.

Feeling hopeless and helpless, the victim withdraws, thus furthering his or her isolation. Eating and drinking habits become irregular, and the victim settles into an increasingly lethargic state. Although the threat to life is not acute, the emotional strain of feeling hopeless is evident over an extended period of time. The victim fatigues easily in order to conserve the energy needed to protect threatened resources from the emotionally overstressful situation (14). The victim remains in a state of chronic fatigue and melancholia, and, with no interest in living, he or she simply dies.

Unlike the curse death in this village, curse deaths in other parts of Africa have been reported to occur immediately after the curse is placed (15, 16). Often only moments after having been pointed out in a tribal gathering, the victim drops dead. These instances often occur in lengthy tribal ceremonies called specifically for the purpose of discovering a transgressor; the victim's anxiety, fear, and guilt are greatly heightened as the ceremony proceeds. When cursed with all the drama of the ceremony, the victim dies suddenly. Many physicians have speculated on the physiological basis of such curse death as well as other types of death caused by emotionally stressful situations (15–22).

In my West African village there are individuals known as *jujumen* who also have the ability to cause harm to others through magic. Unlike the priests, jujumen are not part of the legitimate social system. If a person wishes evil on an enemy, he or she can persuade a jujuman with money and goods to hex the victim. The victim is informed of the hex through a sign, such as powder on a doorsill or owls flying over the house at night. The hex is believed to cause insanity, sterility, infertility, and sickness. Unlike the curse, it can be negated and even reversed by a more powerful jujuman.

DISCUSSION

A number of prerequisites to the success of a curse or hex appear wherever in the world they are found: the victim must believe in the power of the person who administers the curse and must either know or at least suspect that a hex has been placed. The resistance to Western medical techniques both here and abroad might depend on the strength of the victim's belief. In the village I lived in, belief in the power to hex and curse is wholehearted. In areas where the belief is weaker, the victim seems more available to treatment (1). The use of projection and denial by the victim seems to occur when curses and hexes are effective (23, 24). Overdependency and a feeling of powerlessness also occur.

The practice of some churches in the United States presents a similar example of communal belief: priests and elders in these churches often provide total care in the areas of physical and emotional problems (25–28), and exorcisms are not uncommon (29, 30). The communal rejection experienced by the victim of the African curse has its parallel in the European and American practices of shunning, ostracizing, railing, and excommunicating.

However, a religious, tribal, or community belief system is not essential for a curse to be effective. Overdependency on parents rather than on a priest seems to be all that was necessary in certain cases reported in the United States (31, 32). Further, psychophysiological forms of giving up are often seen in hospitals. Patients who suffer a loss of body image due to surgery or an accident or those told of their imminent death have been known to react by withdrawing, eating and drinking poorly, and socially isolating themselves; at times these reactions result in premature death (33). Anorexia nervosa and marasmus may be similar giving up mechanisms (34).

Overwhelming feelings of fright, fear, hopelessness, and helplessness, not unlike those felt by the cursed African, have been known to cause death in the United States when people have been confronted with the demise of a loved one, a business loss, or a dangerous situation (18, 35, 36). "Anniversary" and other forms of sudden and unexplainable deaths might be psychologically and physiologically related (37–39).

The implications of these phenomena might be far-reaching. Further systematic and rigorous research seems necessary and indicated. Research can provide the mental health professional with greater understanding of the powerful influence of culture and society on the individual and the intricate relationship of mind and body.

Patients are often reluctant to tell their doctors about hexing practices for fear of being belittled or not understood. Physicians might be unaware of the existence and importance of these beliefs to their patients. With the continued disaffection and isolation of various minority and ethnic groups in the United States, the trend toward reliance by large segments of the population on indigenous practitioners might be on the increase. An awareness on the part of physicians of the existence of hexing practices within their communities may lead to more reported cases and the development of effective treatment techniques to deal with the psychological resistances and physiological difficulties of patients who have been cursed.

John Stuart Mill on the Liberty of the Mentally Ill: A Historical Note

BY JOHN MONAHAN, PH.D.

The author discusses the quote from Mill's On Liberty *that is often cited by libertarians in opposition to involuntary commitment of the mentally ill. This quote has been taken out of context; other statements in the document indicate that Mill excluded from his libertarian credo those "without the ordinary amount of understanding," i.e., those people who would now be considered mentally ill.*

IN THE continuing debate on the involuntary commitment of persons diagnosed as mentally ill and believed to be suicidal, gravely disabled, or otherwise a danger to themselves, one passage has been quoted repeatedly by libertarians to provide historical and philosophical support for their position. It is the credo of John Stuart Mill in *On Liberty*:

> the only purpose for which power can be rightfully exercised over any member of a civilized community, against his will, is to prevent harm to others. His own good, either physical or moral, is not a sufficient warrant. He cannot rightfully be compelled to do or forbear because it will be better for him to do so, because it will make him happier, because, in the opinions of others, to do so would be wise, or even right. (1, p. 22)

This eloquent statement of the libertarian tradition in its most pure and classic form is cited in virtually every legal, psychiatric, and psychological treatise on the right of the mentally ill to decline intervention that others believe would benefit them (e.g., references 2–4). The statement is interpreted as indicating that to be a true libertarian, one must eschew all involuntary treatment of the mentally ill that is justified by a *parens patriae* concern for their welfare.

The purpose of this communication is to suggest that a fuller reading of Mill's work would lead to the contrary conclusion that he specifically excluded those who would now be called "mentally ill" from the scope of his argument. One is, of course, free to hold that Mill was in error when he declined to apply his libertarian thesis to the mentally ill, much as we today would object to his exclusion of "barbarians" (see below). Yet it should be recognized that Mill himself found nothing inconsistent in applying libertarianism only to those lacking a mental disorder. Quoting Mill in support of the abolition of civil commitment is done out of context and has the effect of distorting the historical record.

In the paragraph following the one typically cited, Mill notes the first exception to his libertarian thesis that only harm involving others is subject to state action:

> It is, perhaps, hardly necessary to say that this doctrine is meant to apply only to human beings *in the maturity of their faculties*. We are not speaking of children, or of young persons below the age which the law may fix as that of manhood or womanhood. Those who are still *in a state to require being taken care of by others* must be protected against their own actions as well as against external injury. (1, p. 22, emphasis added here and in following quotes).

In its most narrow reading, this exemption applies only to children, but it may also be read as applying to others who lack "the maturity of their faculties" and are "in a state to require being taken care of by others." That Mill intended the broader reading can be judged from his next sentences, which constitute a startling example of the colonial racism of the mid-nineteenth century:

> For the same reason, we may leave out of consideration those backward states of society in which the race itself may be considered in its nonage. . . . Despotism is a legitimate mode of government in dealing with barbarians, provided the end be their improvement, and the means justified by actually effecting that end. Liberty, as a principle, has no application to any state of things anterior to the time when mankind have become *capable of being improved by free and equal discussion*. Until then, there is nothing for them but implicit obedience to an Akbar or a Charlemagne, if they are so fortunate as to find one. (1, p. 23)

Later in *On Liberty*, Mill makes the exemption of individuals who would now be regarded as mentally ill more explicit.

> As soon as any part of a person's conduct affects prejudicially the interest of others, society has jurisdiction

When this paper was written, Dr. Monahan was a Fellow in Law and Psychology at Harvard Law School. He is now Assistant Professor, Program in Social Ecology and Department of Psychiatry and Human Behavior, University of California, Irvine, Calif. 92717.

The author wishes to thank Louis McGarry for suggesting the topic and Stephen Morse, John Robson, and Michael Hindus for their comments.

over it, and the question whether the general welfare will or will not be promoted by interfering with it, becomes open to discussion. But there is no room for entertaining any such question when a person's conduct affects the interests of no person's conduct besides himself, or needs not affect them unless they like (all persons concerned being of full age, and *the ordinary amount of understanding*). (1, p. 135)

Finally, toward the end of his treatise, Mill directly addressed the issue of persons who engage in behavior "dangerous to self," clearly holding that the psychologically disordered constitute an exception to his general rule of nonintervention:

If either a public officer or anyone else saw a person attempting to cross a bridge which had been ascertained to be unsafe, and there was no time to warn him of his danger, they might seize him and turn him back, without any real infringement of his liberty; for liberty consists of doing what one desires, and he does not desire to fall into the river. Nevertheless, when there is not a certainty, but only a danger of mischief, no one but the person himself can judge of the sufficiency of the motive which may prompt him to incur the risk; in this case, therefore, (unless he is a child, *or delirious or in some state of excitement or absorption incompatible with the full use of the reflecting faculty*), he ought, I conceive, to be only warned of the danger; not forcibly prevented from exposing himself to it. (1, p. 172)

The full record, therefore, indicates that Mill was quite aware of limits to his libertarian philosophy. He chose to exclude from its range of application those not "in the maturity of their faculties," those "in a state to require being taken care of by others," those without "the ordinary amount of understanding," those not "capable of being improved by free and equal discussion," and those whose behavior was "incompatible with the full use of the reflecting faculty"—in short, those who today would be regarded as mentally ill. Use of the partial citation to the contrary is historically inaccurate.

CLINICAL AND RESEARCH REPORTS

This section contains reports of new clinical or laboratory observations, single cases of unusual interest or importance, descriptions of pilot studies, suggestions for future research, etc. Reports should be submitted in duplicate, typed double-spaced throughout, and may contain 1,000 words, no more than 1 table, and a maximum of 10 pertinent references. Figures cannot be used. Reports will be reviewed by at least one referee and the Editor; the author will receive a postcard informing him/her of the disposition of the submission. Reports will be edited for clarity and conformance with Journal *style.*

An Oral Opiate Antagonist in Chronic Schizophrenia: A Pilot Study

BY DAVID H. MIELKE, M.D., AND DONALD M. GALLANT, M.D.

Several endogenous peptides with biological properties resembling opiates have been isolated from brain. These compounds, chemically classified as endorphins and enkephalins, have been reported to affect a number of behavioral measures in animals, which suggests that their regulation could play an etiologic role in mental illness (1). Beta-endorphins may be the most potent of these compounds: intracisternal injection in rats has induced a rigid immobility (catatonic state) lasting for hours (1). "Wet-dog shaking," similar to that seen with opiate withdrawal, was also observed following lateral ventricular injection of these peptides. The β-endorphin-induced catatonic state and the shaking induced by alpha-, beta-, and gamma-endorphin and met^5-enkephalin were reversed by the administration of naloxone (1).

Jacquet and Marks (2) found that microinjection of β-endorphin in rat periaqueductal grey matter resulted in profound sedation and catalepsy, which led them to suggest that this peptide is an important neuromodulator of the CNS, exerting effects similar to those produced by neuroleptics.

Studies in human subjects have been encouraging. Gunne and associates (3) observed an immediate hallucinolytic effect of naloxone, a narcotic antagonist, in two chronic schizophrenic patients. In a small group of chronic schizophrenic and manic-depressive patients, the levels of two endorphins were measured in serial samples from the cerebrospinal fluid (CSF) before and after treatment with a neuroleptic agent (4). The authors interpreted their results as indicating that endorphins may reach abnormally high levels in patients with chronic psychoses because those patients who responded to treatment showed a decrease in CSF endorphin levels.

Naltrexone is a long-acting potent narcotic antagonist that is effective when administered orally (5, 6). It is approximately 17 times as active as nalorphine and 2 to 3 times as active as naloxone in precipitating abstinence (5). In doses of 50 mg/day, naltrexone exerts a degree of blockade similar to that obtained with 4 mg of oral cyclazocine and has minimal agonistic effects (6). No significant adverse reactions have been observed in clinical studies (7). Forty-eight-hour blockade against 25 mg of heroin has been observed with administration of 120 to 200 mg of naltrexone (8).

Method

The purpose of this study was to evaluate the efficacy and safety of naltrexone HCl in five schizophrenic inpatients, each having at least seven positive items of the 12-point diagnostic scale used by the World Health Organization (WHO). According to the WHO criteria, a minimum requirement of 7 positive items should offer no more than a 1% chance of diagnostic error (9). Subjects were one man and four women, aged 34–47, who had been hospitalized for 5–26 years. All patients displayed florid symptoms of psychosis with active hallucinations at the outset of the study. All patients were free of active medication for 2 weeks before administration of naltrexone. The initial dosage was 50 mg each morning, and the daily dosage was increased by 50 mg per week to a maximum of 250 mg/day in divided doses. The effects of naltrexone were evaluated by the Clinical Global Impression scale (CGI), the Brief Psychiatric Rating Scale (BPRS), and

Naltrexone was supplied by Endo Laboratories, Garden City, N.Y.

the Nurses' Observation Scale of Inpatient Evaluation (NOSIE). Efficacy measures were conducted at baseline and every other week throughout the 6-week evaluation. The laboratory procedures included complete blood count, urinalysis, BUN, SGPT, and alkaline phosphatase and were performed at baseline and weekly throughout the study period. An ECG tracing was obtained each week.

Results

The findings of this exploratory uncontrolled clinical trial suggest that naltrexone, in doses as large as 250 mg/day, is ineffective in alleviating schizophrenic symptoms. Two subjects were dropped when they were receiving 50 mg twice daily because of severe exacerbation of the psychotic process. Three patients were given 250 mg/day in divided doses for 9 days without evidence of symptom remission. The two subjects who were dropped were diagnosed as having chronic undifferentiated schizophrenia. The diagnoses for the remaining three subjects, who were given higher doses, were paranoid schizophrenia (N=1) and chronic undifferentiated schizophrenia (N=2). The CGI, BPRS and NOSIE reflected the lack of clinical improvement.

All patients remained free of side effects. Laboratory findings showed no significant deviations from pretreatment levels and weekly ECGs maintained baseline configurations.

Comment

Although no definitive conclusions can be drawn from the results of a small uncontrolled trial, there appears to be little doubt that naltrexone, in daily doses of 250 mg, is an ineffective treatment for schizophrenic symptoms. One would have to consider the possibilities that naltrexone does not antagonize CNS endorphin activity in schizophrenic patients or that abnormal amounts of endorphins do not have a significant primary role in the production of schizophrenia.

Rapid Treatment of Delirium in Critically Ill Patients

BY DAVID P. MOORE, M.D.

Delirium in the critically ill patient may be life-threatening. Delirious patients may endanger themselves by pulling out tubes and arterial lines or misaligning fractures. Therefore, rapid symptomatic treatment of the delirium is indicated. The following case report describes the rapid treatment of a delirious patient with a regimen used in rapid tranquilization of patients with functional psychoses.

Case Report

The patient, a 34-year-old man, was admitted to the hospital after an auto accident. He sustained second-degree burns over the face, neck, and shoulders, pulmonary contusion, and multiple fractures. A laparotomy revealed a ruptured spleen, and a splenectomy was performed. The patient was placed on controlled ventilation and given morphine and diazepam as needed for pain during burn care. During the first 7 days in the intensive care unit the patient was cooperative, followed directions, and communicated with staff by nodding his head "yes" or "no." On the 8th day he became agitated, struck a nurse, and pulled out his nasogastric tube. Physical and laboratory examinations failed to reveal anything that could account for the change in the patient's clinical state, and diagnosis of delirium of unknown etiology was made. Rapid treatment was started with haloperidol, 10 mg I.M. every hour, with an endpoint of satisfactory remission or limiting side effects.

After he had received 30 mg of haloperidol, there was sufficient remission to allow resumption of routine burn care. There was no evidence of sedation, hypo-

Dr. Moore is Assistant Professor of Psychiatry, Department of Psychiatry and Behavioral Sciences, University of Louisville School of Medicine, P.O. Box 1055, Louisville, Ky. 40201.

tension, or extrapyramidal side effects. A regular regimen of haloperidol was started at a dosage of 15 mg b.i.d. through the nasogastric tube. An order was also given for supplementary doses of 5 mg of haloperidol I.M. every hour as needed for motor agitation and uncooperativeness. Over the next 4 days the supplementary dosage required gradually decreased, and on the 14th day the patient required no supplementary haloperidol. Over the next 5 days the regular daily dosage was tapered, and the haloperidol was discontinued entirely on the 19th day. The patient's subsequent hospital course was unremarkable, and the delirium did not recur.

Discussion

Delirium has been characterized as a syndrome of cerebral insufficiency (1). Optimum management of delirium includes diagnosis and treatment of the underlying cause of the cerebral insufficiency and symptomatic treatment of the delirium itself. Symptomatic treatment may involve environmental manipulation and drug treatment. Environmental measures that are often effective in treating delirium include a continuing relationship with a physician (2), measures to permit adequate sleep (3), placement in a room with windows (4), and provision of clocks, calendars, and night-lights. However, these measures may not produce a sufficiently rapid response.

When rapid attenuation of the delirium is required in order to prevent life-threatening behavior, drugs may be useful. Diazepam, chlorpromazine, and haloperidol have been used in the treatment of delirium (5), but to my knowledge there have been no studies comparing their effectiveness in delirium. By analogy with the functional psychoses, I hypothesized that antipsychotics would be effective in the treatment of delirium.

Rapid treatment of functional psychoses with both haloperidol and chlorpromazine has been effective (6). In one study chlorpromazine was found to be more likely to produce convulsions and severe hypotension than was haloperidol (6). Thus haloperidol would seem to be preferable to chlorpromazine because it is less likely to cause life-threatening side effects. Rapid attenuation of psychotic symptoms can be achieved by giving haloperidol, 5 mg/hour I.M. (6–8). Oral administration is unsatisfactory for rapid treatment because peak plasma levels are not attained for 2–6 hours (9).

Acting on the hypothesis that haloperidol would be as effective in the rapid treatment of delirium as it is in functional psychoses, I have treated three critically ill delirious patients with haloperidol, including the patient described in this case report. Each patient was given 5–10 mg of haloperidol I.M. every hour until either remission or limiting side effects occurred. No patient required more than 30 mg before remission occurred. After the patients responded to the rapid treatment, a regular dosage was started in order to maintain the remission until the underlying cause of the cerebral insufficiency was resolved.

There are no experimentally verified guidelines for deriving a regular dosage from the total dosage used during rapid treatment. I started patients on a total regular dosage equal to the amount used during the rapid treatment. This regimen provided some control of the delirium without causing untoward effects. In order to provide further control as needed, I also ordered supplementary doses of haloperidol, 5 mg I.M. every hour as needed. Supplementary doses were generally required daily for several days to maintain control. Fewer supplementary doses were needed over succeeding days as the underlying cause of the cerebral insufficiency gradually resolved. After any 24-hour period in which no supplementary doses were required, the total regular daily dosage was reduced by one-third. This reduction was continued, providing the delirium did not recur, until the patient was no longer receiving haloperidol. This regimen was successful in alleviating the delirium in all three patients. There were no limiting side effects.

My experience with these three patients indicates that delirious patients may be treated effectively, safely, and rapidly with haloperidol. Controlled studies are needed to confirm this hypothesis. In the meantime, I suggest that consideration be given to the use of haloperidol in treating the critically ill patient with a life-threatening delirium. The number of deaths secondary to self-extubation and other life-threatening behavior might be reduced in this way, and delirious patients might become more cooperative in their treatment.

Suicide in Adolescence

BY PAUL C. HOLINGER, M.D.

Suicide is the second or third leading cause of death in adolescence in many Western countries (1, 2); only accidents and homicides are responsible for more deaths in that age group in the United States (1). However, there are serious methodological difficulties involved in researching and writing about adolescent suicide (3). The observation regarding the lack of case studies and presuicidal data throughout the literature on adolescent suicide (4) is understandable in light of these problems. Notable exceptions include reports by Mason (5) and Sabbath (6).

This paper reports an unusual case of double adolescent suicide in which two brothers killed themselves by hanging in separate incidents within a month. The suicides occurred in institutions that are usually protective—a jail and a psychiatric hospital.

One must consider the multiplicity and interweaving of factors associated with any suicidal outcome. This case, however, highlights three particular issues with corresponding treatment implications: the impact of a suicide on another suicidal adolescent and his family (7), the inadequacy of mobility of investments of the suicidal adolescent (3), and the role of hostility from significant others (6, 8).

Case Report

Ted, a 16-year-old boy, was admitted to the adolescent unit for depression, narcotic use, and stealing. These symptoms had been present since age 10 but had increased markedly and had been accompanied by suicide attempts and psychiatric hospitalization after his girlfriend left him about 1 year before this admission.

Ted's birth and his mother's pregnancy were considered normal. He had three older sisters, two older brothers (6 and 3 years older, the latter named John, after his father), and a younger brother. His parents stated that Ted was different from and slower than the others, noting that he had repeated first grade. The patient characterized his mother as anxious and ungiving and his father, a blue-collar worker, as warmer but unavailable. Ted stated his parents especially valued academic achievement, which prevented him from getting much feeling of worth from them. He attempted to invest himself in his sisters and brothers, particularly John, and his first memory involved playing Lincoln Logs with John and "having a great time." Ted had always met peers as "Johnnie's younger brother" and saw himself in that way. He felt that John had "everything one needed to be popular: broads, drugs, music, looks, and money."

Ted was hospitalized for 5 months. There was no evidence of thought disorder or psychosis, and he initially displayed a quality of bravado. He and his family, particularly the parents, engaged in intensive treatment aimed at establishing a therapeutic alliance and dealing with his massive depression and feelings of dependency, rejection, inadequacy, and rage. After he was discharged, Ted did well for 3 months, at which time a recurrence of the admitting symptoms prompted a search for rehospitalization.

During this search, John was jailed overnight for drug possession, and it was thought that he may have ingested other drugs, including barbiturates, to prevent the police from finding them. That night, John committed suicide in jail by hanging himself.

Initially, Ted appeared to have integrated around the suicide. He saw himself as having a mission, i.e., helping his parents through the crisis, and he functioned well. However, the initial integration slowly became suspect, particularly in the face of the parents' continued glorification of John. Ted described a "weird" feeling being in John's room, took over the use of his car, and occasionally wore his clothes. Six weeks after his brother's death, Ted was jailed for a minor traffic violation. His mother physically fought with Ted when she was paying his bail, reportedly screaming "I wish you had died instead of your brother Johnnie," and "God took the wrong one." The next day, self-destructive gestures with a rope and an overdose precipitated Ted's emergency admission to another psychiatric hospital. He soon began to seem less depressed and to talk about future plans. However, 5 days after his admission Ted slipped away when the staff's attention was diverted and was found hanging by his belt in the shower room. He was in coma and died 24 hours later.

Thereafter, therapeutic efforts were aimed at preventing further deterioration within the rest of the family, and the parents started supportive treatment. Ted's mother was especially guilty about the relief she felt with Ted gone and her physical safety and that of her possessions assured.

Discussion

Although one must keep in mind the multidetermined nature of suicide, three specific issues in this case warrant particular attention. First, with respect to the impact of the suicide the phenomenon of two adolescent brothers committing suicide within a month by the same method is important. Ted's integration around his idealized brother's death is noteworthy. This integration seemed to develop through

When this work was done, Dr. Holinger was with the Institute for Psychosomatic and Psychiatric Research and Training, Michael Reese Hospital, Chicago, Ill.; he is currently a Fellow at Harvard University, Cambridge, Mass. Ted's increasing sense of mission in regard to his parents and through increasing identification with his dead and glorified brother. He tried to take his brother's place and identity in the family and grasped for some sense of self-worth. Treatment implications include the need for awareness of the potentially critical nature of such an integration around a sibling's suicide and for the availability of treatment for the parents as well as the surviving adolescent.

Second, Haim (3) noted that adolescents usually can perform the work of mourning that results from narcissistic wounds, damage to the ego ideal, and object losses. However, suicidal adolescents have inadequacy of mobility of investments, i.e., inability to disinvest the disappointing or lost object. Despite the pain, they maintain their investments, repeat their behavior, and brood on their disappointment (3). Ted manifested a marked inability to disinvest his parents because of the nature of his attachments to them and the unavailability of different channels of investment. His other major investment became his brother John and the delinquency subculture that John valued. Throughout treatment there was some evidence of investment in and idealization of the therapist and staff. Treatment implications include the necessity of mobilizing, and being able to tolerate, idealization by such patients.

Third, the role of hostility from significant others has been studied less than the patients' hostility turned inward. Sabbath (6) proposed the expendable child concept, which presumed a parental wish, conscious or unconscious, interpreted by the child as a desire to be rid of him. Gould (9) contended the core factor in the formation of a "suicidal personality" in adolescents was the felt loss of love. Rosenbaum and Richman (8) found more extreme hostility and less support in families of suicidal patients than nonsuicidal patients. Ted's parents saw him as "different," if not unwanted, and the reported eruption of overt hostility was striking. Sabbath (6) extended the expendable child concept to that of the expendable patient in terms of staff-patient or doctor-patient relationships, and Havens (10) described unconscious desires on the part of the staff to get rid of a hospitalized adult patient who later committed suicide. Such reactions, best understood as countertransference phenomena, were present in the therapist and staff in the case described here. Treatment implications include recognizing, understanding, and working through such transference and countertransference reactions, in addition to helping the family and patient to understand the role of expressed hostility.

The Capgras Syndrome as an Adaptational Maneuver in Old Age

BY ALVIN I. GOLDFARB, M.D., AND MARCELLA BAKUR WEINER, ED.D.

Capgras and Reboul-Lachaux in 1923 first described a syndrome of failure to recognize a familiar person coupled with the belief that he or she was a "double" who was similar to the original person but an impostor (1). The syndrome has been described in persons with paranoid and manic-depressive psychoses and other conditions; it is usually attributed to ambivalent emotional attitudes toward the person whose real identity is denied.

The Capgras syndrome has caught the attention of many authors (2–4). It was believed that the patient's feelings of strangeness (anxiety) about the familiar others led to this state of nonrecognition. Depersonalization and unreality factors have been proposed as explanations for the syndrome (5).

This paper was presented at the 29th annual meeting of the Gerontological Society, New York, N.Y. Oct. 13–17, 1976.

Until his death on June 11, 1977, Dr. Goldfarb was Associate Clinical Professor of Psychiatry, Mount Sinai School of Medicine, and Associate Attending Psychiatrist, Mount Sinai Hospital, New York, N.Y. Dr. Weiner is Adjunct Associate Professor, Department of Applied Human Development and Guidance, Teachers College, Columbia University, New York, N.Y. 10027.

Unconscious libidinal drives also have been suggested as the underlying force in that the syndrome may be a "defense reaction" against the unleashing of forbidden impulses (1). The other person is denied, negated, or rejected through the use of defenses such as projection and identification. Three factors characterize this conceptualization: 1) the impostor is a person of importance to the deluded one, 2) the pretender is not equal to the impersonated other, and 3) attempts to deal with the anxiety seem to lead to the delusion. Although some of the afflicted persons were "confused" and "disoriented in time," most of the patients described by the authors cited seem to have been cognitively intact. Observers noted that often the perceived "double" resembled the misidentified person in the past. The "illusion of doubles" is thus rooted in a "change of consciousness marked by a double attitude toward the present and past experience" (4).

In our experience, the Capgras syndrome occurs with frequency in association with those difficulties of memory and learning classified as organic brain syndrome (OBS) or dementia. The illusion of doubles has been cited as "an example of delusional misidentification," a state of nonrecognition or inability to properly identify a person well-known and personally related to the afflicted individual. This double is always an important person, and the patient does not misidentify others. The double is usually accused of not having the virtues the patient would like the "original" to possess. The dynamics thus appear to be an adaptive solution by way of communicating that the accused person is in need of change, i.e., should be different than he or she is (6). The following cases present some examples of the syndrome.

Case Reports

Case 1. A man of 78, Mr. A, was found wandering in the streets. Taken to the police station, he said that he was looking for his wife. When his wife was telephoned and spoke to him, he said, "That is not the wife I'm looking for." Apparently, he acknowledged that he had a real wife whom he had left to find another who would be more gratifying. Although he did not call his wife an impostor, she was nevertheless "not his wife." His behavior may be interpreted as a coping attempt. Such an attempt at mastery is a search for aid, a search for a beneficent relationship, whether or not it was experienced in the past; it is an indication of the need for a dependent relationship (7).

Case 2. Ms. B, a 78-year-old woman, accused her husband of being an impostor. She stated that she did not want him in the house. Whenever he left the house (e.g., to empty the garbage), she locked the door and would not allow him back in. In order to gain access to the house, he had to call their son or neighbors or plead with his wife to let him in. He was constantly the target of her abuse and accusations. She also called her son to complain about the interloper, the impostor, and could not be convinced of his identity.

He had been and remained a demanding and intemperate person unable to put up with his wife's many shortcomings, which had increased with her progressive memory loss. He could not understand her current difficulties as being related to this irreversible memory loss. She, in turn, bitterly resented his critical attitude. In the past, she had always both respected and adulated him, restraining any criticism or opposition out of fear.

In treating the couple, it was pointed out to the husband that his wife was reacting to his seeming criticism of her by putting blame onto him, saying, in effect, "You aren't the husband that I had, the one who understood me. Therefore, you are a stranger to me." It was explained that she could not help forgetting things but that he could not be blamed if he occasionally lost his temper, and he was told that it would be helpful for her if he were nonconfrontational and supportive. The son received similar explanations.

Discussion

The Capgras syndrome, as described in the cases cited, appears to be a common elaboration of a desire to recapture a dependent relationship with a close associate that has been lost either because there has been a change in one's needs or in the character of the previously supportive person. It is understandable as an attempt to find personal assistance, emotional support, and reassurance on the part of one who feels frightened and weak from another who is delegated to behave in a supportive way. The behavior of the aged person displaying the Capgras syndrome may be regarded as motivated and determined by the patient's current emotional and physical status, his or her life situation, personal expectations, and past patterns of adjustment. The motive is to reconstitute the environment by replacing the current, nongiving, nonacceptable one with a nurturant, giving, and acceptable one. Such behaviors can be understood as adaptive attempts. Thus, the Capgras syndrome is a clear-cut and easily understood elaboration of the individual's attempt to force, to gain, to manipulate, and to get from another person that which he believes is coming to him. It is therefore not necessarily an indication of idiosyncratic personality difficulties in the aged person or of specific psychotic states such as paranoid or manic-depressive psychoses, as many have suggested (2–4). Rather, this syndrome may occur (as it does in older persons) whenever there is a decrease in discriminatory capacities (7).

Conclusions

The perception of imaginary differences and imaginary resemblances with respect to persons well-known to an elderly individual is frequent and can be understood as based on subjective distress, unhappiness with an existing relationship, desire to change, and attempts to signal the need to alter transactions and to find what is now lacking in the people around them. Therapeutic intervention based on an understanding of

this phenomenon can lead to reduced intensity of symptoms in the patient and comfort to both him and his family.

Lithium in the Treatment of a Child Abuser

BY BARRY M. PANTER, M.D.

In this article I will report the use of a new treatment approach, lithium, in the case of a woman who abused her children. The decision to use lithium was based on several factors. The child abuse and other destructive acts occurred while the woman was in a rage, and Sheard (1) has found lithium to be effective in the control of rage reactions. Rifkin and associates (2) reported that lithium helps to dampen affect in patients with the diagnosis of emotionally unstable character disorder; my patient described changes in mood consistent with cyclothymic personality or mild manic-depressive illness. Phenothiazines, antidepressants, and minor tranquilizers had not been helpful. The patient's downward spiral into destructive impulse and action produced a sense of desperation in everyone involved.

At the time lithium therapy was started with this patient, there were no reports of this use of lithium in the literature. Recently Kerr (3) reported a similar case in which aggressive outbursts and child battering ceased when his patient was stabilized on lithium.

Case Report

Ms. A was 30 years old when she was referred for treatment because of frequent verbal and physical family fights, which were often followed by Ms. A's sullen withdrawal, drinking and driving, and abuse of her children, Annie, age 4, and Joey, age 7. The need for intervention was recognized by Mr. and Ms. A.

Her destructive behavior erupted after the family moved close to Ms. A's parents, which reactivated repressed conflicts and contributed to Ms. A's psychological and behavioral decompensation.

Ms. A is the older of two girls. Her sister was the "good," favored child, and she was the "bad," neglected one. Her mother was promiscuous and habituated to pills for pain and insomnia. Ms. A felt that her mother used her like an object. Her father was withdrawn and not interested in her. Ms. A recalled that when her feelings were hurt she became angry and cruel; she pulled wings off butterflies and smashed the heads of cats. When she was 9 her father began to punish her by pulling her pants down and spanking her. She was excited by this and looked forward to the spankings, feeling guilty about the shared activity with her father and relieved by the pain.

During the years between ages 10 and 18 she was sexually involved with a male friend of the family who was her father's age. He was also her mother's lover. Her mother knew of and encouraged the sexual relationship: "If my mother couldn't be with him, she would send me in her place." Ms. A felt excited by the sex, grateful for the male attention, and guilty. Her sense of herself as the bad child was greatly reenforced.

At 19 she was hospitalized for several months with the diagnosis of schizophrenia. Soon after her discharge she married Mr. A, a successful sales representative for a large retail corporation who is often away from home because of business. When he is home, Ms. A resents him because "He tries to run my life. Everything has to be the way he wants it. He treats me like I'm his slave."

Ms. A had many psychiatric symptoms prior to the move close to her parents. She abused both children, especially her son. They occasionally needed X rays and medical attention for contusions and bloody noses. There were no fractures or hospitalizations. The abuse occurred during "fits of anger." She said, "I meant to stop him from doing something bad, and then I couldn't stop myself from hitting him. I became confused." She drank to "get away from the things that bugged me and to calm myself." She had several phobias that occasionally prevented her from leaving the house. After the family move, the symptoms became worse. She felt her mother treated her unfairly. Her husband was "home and controlling me." Additional symptoms appeared—she hallucinated cameras and eyes watching her and heard female voices telling

The author would like to thank Dr. Theodore Van Putten for his valuable assistance with this case.

her she was bad and should kill herself. She withdrew into fantasy for days at a time. She enjoyed and was reluctant to leave her self-destructive fantasy world because "At least I control what happens there."

Course of Treatment

The first goal of treatment was to protect Ms. A and her children. Repeated hospitalizations for overdoses and assaultive behavior in the past had done this but little more. There was no clear improvement in her behavior or psychotic thinking on daily doses of 1000 mg of chlorpromazine, 60 mg of trifluoperazine HCl, 800 mg of thioridazine, 40 mg of haloperidol, or 200 mg of doxepin HCl. Extrapyramidal side effects, sedation, and dryness of the mouth were present but minimal. These drugs did not improve the target symptoms of dangerous behavior and psychotic thinking.

The hospitalizations, which varied from several days to 5 months in duration, followed abuse of the children, drinking, or self-destructive acts. The self-destructive acts never consciously distressed Ms. A. She felt that she had gotten something bad out of herself, and was relaxed and calm afterward.

During a later hospitalization, lithium was prescribed, and her rage, assaultiveness, and self-destructive behavior diminished greatly. (The effect of lithium on her behavior is shown in table 1.) She has struck her children twice since she started lithium treatment, but these episodes were, by her description, qualitatively and quantitatively different from those which had occurred before. She was able to gain control of herself quickly and did not hurt the children.

Her lithium level is maintained at 1.3–1.5 mEq/liter on a dose of 1800 mg/day. She has been hospitalized twice in the 2 years since she started on lithium, first after an overdose of analgesics and sleeping pills (serum lithium=0.8 mEq/liter) and then after she reported having taken steps in a plan to kill her parents (serum lithium=0.7 mEq/liter). Episodes of psychotic thinking still occur, but she is not impelled to act on these thoughts as she was before.

Ms. A listed the following effects of lithium:

> I am more amenable to suggestion and make positive efforts to change the situation. When I'm off the lithium I find it easier to stay depressed. My suicidal feelings are present but I don't feel the push within me to actually do it. I get angry but I don't lose control of myself. I have not become enraged.

Discussion

The psychodynamics of much of what was happening to Ms. A were clear early in the course of her treatment. Her ability to test reality was intact most of the time. Under stress she regressed to a psychotic state in which primary process was dominant. She was unable to control her behavior and often acted on her psychotic thoughts. Her sense of self was of being incomplete, vulnerable, bad, and threatened, which led to great anxiety. She needed the presence of and fusion with the significant other—mother, husband, or child—to relieve the anxiety of separateness. However, she felt that fusion meant being controlled and used, which enraged her and led to the aggressive outbursts. During the psychotic regressions she often was unable to distinguish between herself and others. She projected the "badness" into her children and then attacked it. When enraged she was not able to distinguish clearly who was being beaten. These violent acts of child beating, wrist slashing, and window smashing represent a fusion of sexual and aggressive drives and a fusion of self and other. The violent act gratifies the fused drives and, insofar as it is self-destructive, atones for the gratification at the same time. The diagnoses of explosive personality and habitual excessive drinking describe Ms. A's past behavior. The most useful psychodynamic diagnosis is Kernberg's borderline personality organization (4).

This understanding of what was happening was not useful to her initially. The tenuous control that her fragile ego could exert on her behavior was overthrown by the onslaught of her rage. Each outburst was followed by guilt-ridden withdrawal and psychologic decompensation. Lithium decreased the intensity of these emotions and she no longer was impelled to act on them. Her ability to control her behavior has enabled her observing ego to develop. As she has gained understanding of herself and her relationships, her anxiety has diminished. She relates to others with less distortion of reality and consequently with less aggression. Since she has been taking lithium, she has been able to provide a safe and adequate environment for her children and her husband.

TABLE 1
History of Destructive Behavior Two Years Before and Two Years After Lithium Therapy

Behavior	Before Lithium	After Initiation of Lithium Therapy
Striking children*	2–3/week	2 (total)
Hospitalizations	11	2
Total hospital days	357	11
Overdoses	10	1
Breaking windows	15	0
Slashing wrists	10	0
Drinking*	daily	rarely
Episodes of drunkenness*	3–4/month	1 (total)
Episodes of rage*	4–6/week	0

*Estimates based on patient's and husband's reports.

Is There a Role for Medical Ethics in Postgraduate Psychiatry Courses?

BY MICHAEL JELLINEK, M.D., AND DEAN PARMELEE, M.D.

Medical ethics is receiving increasing public and professional attention. Discussions of ethical issues are now a part of many medical school curricula and residency training programs. However, in informal review of postgraduate psychiatry courses, we found that ethical issues were given little or no attention. Is there a lack of relevance or interest in ethical issues among practicing psychiatrists attending postgraduate courses? Are there technical difficulties in constructively sharing ethical perspectives?

We decided to explore these questions at the Harvard Medical School-Massachusetts General Hospital postgraduate course in psychiatry. The three goals of the study were to determine the level of interest in ethical issues, to define specific topic interest, and to evaluate several educational techniques.

Method

All participants in the postgraduate course were given a 1-page questionnaire entitled "Ethics Seminar," stating the general goals of the seminar and a listing of major topics and subtopics (see table 1). Participants were requested to indicate areas of interest and suggest further topics.

The seminar lasted for 1 hour and was recorded. The format for the seminar included a brief introduction and presentation of case studies (1, 2), both chosen on the basis of questionnaire responses.

Results

Of the 85 participants in the postgraduate course who received the questionnaire, 43 returned them; 25 stated that they planned to attend the seminar but only 13 did so. Table 1 gives the number and distribution of responses by topic and subtopic. There was no significant difference in areas of interest between those who attended the seminar and those who did not. "Confidentiality" and "emergency room issues" were the two topics of major interest; subtopics generating the most responses were "third-party payers," "informed consent in private practice," and "forced administration of medication." On the average, each respondent indicated five subtopics of interest. In addition, participants wrote in the following subtopics: management of physician's misconduct, rights of minors and parents, and premature/inappropriate discharge of patients. Participants related anecdotal data from their clinical work, sharing experiences that were common for the psychiatric practitioner. Legal mandates often dominated ethical decision making, and a variety of other factors, such as family wishes, patient's future employability, and specific psychiatric pathology, were secondary. Consideration of abstract ethical concepts and precedents played a minor role.

TABLE 1
Ethical Issues Questionnaire

Topics/Subtopics	Responses	
	Number	Percent
Confidentiality	64	29
Third-party payers	28	13
Inpatient records	18	8
Outpatient records	18	8
Informed consent	35	16
Research	7	3
Private practice	28	13
Contract with patients	37	18
Physician/patient responsibilities	21	10
Implications for patient trust	16	8
Emergency room issues	82	37
Who do you serve?	12	3
Financial consideration	7	3
Use of security	15	8
Commitment	20	10
Forced administration of medicine	28	13

The discussion concerning confidentiality focused on one specific question: How much and what kind of information should be released at a patient's request? If one releases "too much," the patient's future employability or insurability may be jeopardized; if "too little" is released, the third-party payers may not reimburse and the patient's future physician may not have adequate information. In other words, should the physician do what he feels is in the patient's best *medical* interest, or should the physician include social, economic, and legal factors in decision making?

The discussion of forced administration of medication raised many questions. Does the psychotic patient have the right to refuse medication, or is it the physician's responsibility to do what is in the patient's best (medical) interest? What is the physician's responsibility to society or to other patients on a ward if a patient is dangerous? For the most part, participants felt that such questions were interesting but that their decisions in daily practice were made in the context of the individual case and with the feeling that the legal system should make the final determination.

The authors wish to thank Dr. W. Anderson for his support and encouragement.

Discussion

Approximately one-half of participants in this postgraduate course expressed an interest in medical ethical issues. Especially prominent were the areas of confidentiality, the role of third-party payers in health care delivery, and forced administration of medication. Thirteen physicians felt sufficiently motivated to attend the elective seminar, which was held at night and was in competition with other traditional seminars held simultaneously.

The seminar/discussion format is a useful medium for practitioners to explore ethical perspectives and decision-making processes. The discussion group quickly developed a sense of warmth, reflecting both the level of tension and confusion as well as the benefits of sharing common clinical dilemmas.

We saw two problems in the seminar as an educational method: 1) The sharing of anecdotal material did not easily give way to consideration of more abstract ethical concepts. 2) Participants needed more information and guidelines to separate legal, economic, social, and ethical perspectives in problem solving—case studies alone were not helpful. It is possible that a formal lecture in advance of the discussion group would create a more suitable framework for these considerations.

In conclusion we feel that the complex nature of ethical problems, the level of practitioner's interest, and the benefits of the discussion group strongly suggest that ethical issues be included in postgraduate psychiatry courses.

Paroxysmal Kinesigenic Choreoathetosis or Hysteria?

BY DAVID A. WALLER, M.D.

Paroxysmal kinesigenic choreoathetosis (PKC) is a distinct neurologic entity characterized by recurrent, brief, stereotyped attacks of involuntary bizarre posturing and writhing (1). Attacks are induced by movement after a period of immobility and are sometimes so violent that the patient is hurled to the floor. There is no loss of consciousness, amnesia, or EEG abnormality before, during, or after an attack, and examination between attacks reveals no neurologic findings (2). A physician unfamiliar with this entity is likely to consider the phenomenon hysterical and to treat the patient exclusively with psychological approaches, thereby denying him or her the demonstrated benefits of medication (1, 2).

Case Report

A 22-year-old woman college student came to the neurology clinic of a large general hospital for definitive diagnosis and management of a "seizure problem" she had had since age 8. She stated that a neurologist in her hometown had diagnosed her as having "paroxysmal choreoathetosis" and had treated her with diphenylhydantoin. The number of seizures had increased recently. She also had had psychiatric treatment for a variety of problems seen as either provoking or stemming from her seizures. While a history was being elicited, she doubled over and her right hand and leg writhed for about 5 seconds. There was no loss of consciousness. She then sat up and continued to speak. She described an aura of "feeling like her leg was going to sleep" before severe attacks. Neurologic examination was unremarkable, as were skull X rays, computerized tomography, and waking and sleeping EEGs. Although she claimed to be taking diphenylhydantoin as prescribed, the serum phenytoin level was trace. Mental status examination was unremarkable other than mild blocking that was not associated with psychotic symptoms. As she was leaving the office at the end of a follow-up visit, she suddenly dropped to the floor and started to writhe. When asked to stand up, she arose and walked from the clinic. The diagnosis of hysteria was made, and she was referred to the psychiatry service.

During psychiatric evaluation she had several attacks that seemed to confirm the diagnosis of hysteria, in view of the absence of change in consciousness, postictal amnesia or confusion, or abnormal EEG findings, and the presence of psychological conflicts. Review of the literature on paroxysmal choreoathetosis, however, pointed to this as the correct diagnosis for several reasons: the stereotyped nature of the attacks, precipitated by movement and corresponding exactly

Dr. Waller was Resident, Department of Psychiatry, Massachusetts General Hospital, when this work was done; he is now Assistant in Psychiatry, Children's Hospital Medical Center, 300 Longwood Ave., Boston, Mass. 02115; and Instructor in Psychiatry, Children's Hospital Medical Center-Harvard Medical School.

The author wishes to thank James E. Groves, M.D., for assistance in the preparation of this manuscript.

to Stevens' sequential photographs of attacks (2); movements beginning in the distal portions of the limbs and progressing to violent thrashing that lasted 15–30 seconds; onset during childhood; family history of a sister with an apparently mild form of the disorder (paresthesias that rarely progressed to movements); history of an initially good response to diphenylhydantoin; and, finally, the characteristic absence of other neurologic findings. She was therefore referred for further evaluation by a neurologist who specialized in movement disorders.

The neurologist confirmed the diagnosis of PKC as definitely as was possible in the absence of any known definitive laboratory data and placed the patient on 400 mg/day of diphenylhydantoin. Follow-up in both psychiatry and neurology clinics was advised. In a subsequent psychiatric visit, the patient stated that since she had resumed diphenylhydantoin the number of attacks had decreased strikingly from three or more severe attacks a day to three severe episodes in the 3 months she had been on the medication. Guilt-stricken, she confessed that before her initial visit to the neurology clinic she had not been taking her medication as prescribed. She did not know why. Further psychiatric treatment was advised to deal with her difficulty in accepting help for her disorder, but she was lost to follow-up shortly thereafter.

Discussion

In an overview of the diagnosis of hysteria, Chodoff noted that the term "hysterical," as applied to physical symptoms, initially meant "of nonorganic origin" (3). The term then took on added meanings, and more recent articles on hysterical convulsions have suggested designating them "nonepileptic seizures" or "pseudoseizures" (4, 5) and have provided criteria for suspecting such psychogenic convulsions (4, 5). A diagnostic problem arises in that PKC is descriptively a type of pseudoseizure, which is nonetheless of presumed organic rather than psychological etiology. In a report of cases in Taiwanese immigrants, Jung and associates (6) summarized the evidence for and against classifying PKC as a seizure disorder and concluded that accurate classification is impossible with present information. The effectiveness of various anticonvulsant medications (7) argues in favor of an epileptic phenomenon, while the demonstration that L-dopa is effective (8) supports the theory that it is an extrapyramidal disorder. Two cases that came to autopsy did not show definite structural alterations in the brain (1, 2). Depending on one's confidence in the classic descriptors of PKC, the differential diagnosis between it and hysterical conversion is almost impossible unless there is a history of onset in childhood. Cases of hysterical seizures generally do not begin before puberty (4, 5), but the onset of PKC is usually between the ages of 6 and 15 years (9). By this criterion the case I have described is one of paroxysmal kinesigenic choreoathetosis. PKC should be distinguished from the dystonic form of paroxysmal choreoathetosis, a less common disorder first defined by Mount and Reback (10). Paroxysmal dystonic choreoathetosis usually begins in infancy, and individual attacks may last several hours and are not induced by movement (9).

Although cases in only one member of a family have been documented, PKC often appears in a familial pattern compatible with that of an autosomal dominant trait with low penetrance (6). There is a tendency toward spontaneous remission over time. The apparent organic nature and pharmacologic response of PKC do not diminish the importance of psychological aspects. Emotional stress seems to act as an added precipitant to attacks (1), and patients who are motivated can learn techniques by which they can consciously suppress an imminent attack (6). Kertesz described several patients with PKC as anxious or depressed; one committed suicide (1). In the present case, once the number of attacks was reduced pharmacologically, emotional aspects caused the patient to reject needed treatment.

Atrial Myxoma Masquerade

BY RALPH N. WHARTON, M.D.

In the general hospital, the consulting psychiatrist is often called on when no "organic pathology" can be found. After extensive medical assessment by a variety of specialists a patient may be advised as a last resort to seek psychiatric help for a panoply of symptoms of an evanescent and sometimes apparently hypochondriacal nature. The true hypochondriac is encountered not infrequently, but so are patients who present with a variety of diffuse aches and pains and weight loss that are related to an underlying tumor which does not become clinically apparent for months. In general, there is an intertwining of both psychological and organic pathology at the time of referral.

There are always new diagnostic entities and novel situations that test the mettle of consultants, demanding the highest clinical acumen. Long-standing psychopathology of substantive proportions often complicates a difficult new situation. When a variety of opinions has been given by physicians in several settings, the patient's conflict may grow and the initial psychological problems may be compounded. In this paper, I will describe the case of a patient who represents a unique combination of all of these problems.

Case Report

A 50-year-old married, childless woman lawyer was admitted to the Columbia-Presbyterian Medical Center in New York City 10 days after the onset of *left-sided* weakness and aphasia that had cleared in a suburban hospital in 2 to 3 hours. An echocardiogram at that facility showed possible evidence of an atrial myxoma.

History. The patient's father and mother-in-law had both died after cerebrovascular accidents in the summer of 1972 following long illnesses. Although she was upset emotionally then and thereafter, the patient did not consult a physician until July 1974.

At that time she complained of an episode of sweating, nausea, and transient blurring of vision that lasted about 1 hour. Her pulse was somewhat rapid (80 beats per minute) and she had a mild, faint tremor. On her second visit to her personal physician she was told she had mild hyperthyroidism and was treated for 3 months with methimazole through October 1, 1974.

In late October she had a second episode of tremor, dizziness, and *left-sided* weakness, as well as insomnia that persisted for several weeks. She was seen briefly at another hospital and given 10 mg of diazepam for sleep. No physical abnormalities were found at the time of that examination. Subsequently she became afraid to go anywhere without her husband, although she was repeatedly reassured and told that nothing was medically wrong. In February 1975, she had a hysterectomy in a suburban hospital for "fibroids." In May 1975, after an episode of weakness, tremor, and dizziness, she was admitted to another hospital and told she had had a slight stroke. She had lost 9.1 kg in 6 months and developed transient *right-sided* weakness on the day of admission. After discharge, she again became anxious and consulted another New York City neurologist, who could find no evidence of a stroke. She also consulted an internist who could find no evidence of thyroid, heart, or vascular disease.

In July 1975, on referral by her initial physician, she consulted a psychiatrist who prescribed diazepam and amitriptyline. Her three sessions with him were stormy. She reported being told she was the angriest woman the psychiatrist had ever seen, and stopped treatment after the evaluation sessions.

Her internist, who continued to see her every 6 months, referred her to me for evaluation in late September 1975. When I first saw her, the patient was obviously depressed, anxious, and angry. Mental status exam did not reveal any thought disorder or impaired judgment. There were no difficulties in orientation, counting, or calculation. The patient's identification with the members of her family who had suffered strokes was obvious and seemed to account for part of her overreaction to the physical symptoms. Her anger at her physicians and confusion about her illness prevailed. I saw her twice weekly at first and then biweekly for 40 sessions over the next 15 months before the diagnosis of atrial myxoma was finally made. The psychological issues of import included her past conflict with her father over her authorship of his will, conflict with her husband over their joint law practice, and finally by a move to a new home in July 1976.

During the period of psychotherapy, the patient regained 4.54 kg and returned to work for 2- and 3-month periods before her symptoms in December. Her appetite, sleep, and mood had generally improved, but the nocturnal palpitations and "anxiety" persisted. She was reassured by her internist on three different occasions that she did not have significant cerebrovascular disease or notable heart disease. During my summer vacation, the patient had a moderate recurrence of insomnia and again consulted the internist.

Hospital admission. During a Christmas party and after a few drinks, the patient's husband frantically called me, saying his wife had had a stroke and was being admitted to a hospital in New Jersey. I visited the hospital and examined the patient. It was obvious that all her symptoms had cleared again within hours. Also, there was apparently no new psychic stress. Another medical conflict ensued: the physicians insisted

Dr. Wharton is Associate Professor of Clinical Psychiatry, College of Physicians and Surgeons, Columbia University, 622 West 168th St, New York, N.Y. 10032.

that she have prompt bilateral arteriograms and heparin; the patient refused and I supported her decision. A plan was arranged for her to have no invasive tests and to be transferred to New York City. In the waiting period, an additional cardiac consultation was arranged. At that time, the suggestion of a myxoma was considered and an echocardiogram was done.

Angiocardiography at Columbia-Presbyterian Medical Center was confirmatory. The patient underwent surgery on January 6, 1977, and a 3×4×2 cm pedunculated atrial myxoma arising from a 1½ cm base just at the lower end of the left side of the foramen ovale was removed; a ball valve-like mechanism was apparent. Pathological examination showed a classical atrial myxoma; 44 minutes of cardiopulmonary bypass were required for excision.

Discussion

Atrial myxoma is the most common (50%) intracavitary cardiac tumor (1). The first successful angiographic diagnosis of myxoma was made in 1951 (2). By 1965, there were 350 recorded cases in the literature, ranging from infants to the elderly; currently there are well over 1,000. Approximately 75% were seen as occurring in the left atrium (3) and represented 35%–50% of primary cardiac tumors. Most occurred in patients between the ages of 30 and 50. The effects of the tumors (4) may be due to 1) primarily mechanical obstructive symptoms that may be intermittent, 2) embolic phenomena, or 3) nonspecific symptoms such as weight loss.

This patient presented all of these manifestations. Syncope, when the patient is upright, is common with intracavitary cardiac tumors, as are dyspnea and atypical chest pains. This patient's difficulties resulted in nocturnal palpitations due to mechanical factors associated with her tumor as well as to emotional concomitants. Even after surgery, some mild nocturnal anxiety persists. However, the palpitations that resulted from obstructive effects of her tumor are no longer present. The patient no longer demands her husband's constant presence. The coincidence of psychiatric factors in this case obviously complicated the diagnosis.

The patient continued psychotherapy and antidepressant medication after surgery. Her early responsiveness to the psychotherapy made the diagnosis more difficult early in treatment. The delay in diagnosis was due in part to the intermittent nature of the symptoms and the difficulty in hearing the cardiac sounds; the crucial diagnostic clue was the tumor on a pedicle creating a unique noise when the patient was in a particular position. The changing side of the weakness (first left, then right) was an additional missed clue misinterpreted as psychological.

I was perplexed by the persistent palpitations and the physical symptoms that resulted in the periodic visits to the internist, who had never seen a case of myxoma. Echocardiography might have been used sooner had the course or physical findings been different.

It is important for consultants to consider atrial myxoma in patients with transient syncopal attacks, episodic weakness, and/or atypical nocturnal palpitations. Echocardiography (5, 6) adds special crucial evidence in the 30–50 age group in the presence of puzzling, transient, ischemic-like attacks.

Patient Responsibility and the AMA Discharge: A One-Year Follow-Up Study

BY DAVID J. WITHERSTY, M.D.

Outcome studies of discharges against medical advice (AMA) have described posthospital adjustment as being the same for AMA patients and non-AMA patients (1, 2). A recent study of AMA discharges using a matched non-AMA control group found little difference in posthospital adjustment and suggested that AMA discharges might be therapeutic (3).

The Behavioral Medicine Inpatient Service at the West Virginia University Hospital (described elsewhere, see references 4–6) offers a unique opportunity to study the AMA discharge. The service is totally open, with no seclusion rooms or locked doors, and admission is voluntary. Patients are expected to take responsibility for making decisions regarding admission and discharge. Furthermore, they are told that they are expected to take responsibility for making

Dr. Withersty is Associate Professor, Departments of Internal Medicine and Behavioral Medicine and Psychiatry, West Virginia University Medical Center, Morgantown, W.Va. 26506.

The author wishes to thank Ms. V. Kerrigan for her help in the preparation of this manuscript.

changes in their maladaptive behavioral patterns.

Under such conditions, one would expect AMA discharges to be high. This is the case—approximately 20% of the patients leave against medical advice. Although results of two one-year follow-up studies suggest that it is therapeutic to place primary responsibility for admission and discharge decisions as well as behavioral change with the patient (5, 6), one must question what happens to those patients who elect to leave the unit against medical advice.

The remainder of this article will present data that were obtained in a one-year follow up study of AMA patients compared with data obtained in previous studies of non-AMA patients.

During the period between March 1975 and August 1975, 480 patients were admitted to the inpatient service: 99 patients left against medical advice during that time. The age of AMA patients ranged from 15 to 68 years (mean=32.5). The average number of days on the unit was 4.7, compared with an average of 14 days for other patients. Of the 99 AMA patients, 38 had been hospitalized on the inpatient service of the West Virginia University Hospital before the present admission. Thirty patients had been hospitalized previously on psychiatric units at other hospitals and so had no previous hospitalizations elsewhere (data on admissions to other facilities were unavailable for 9 patients).

Prior to discharge 71 of the 99 patients had attended at least one session of group therapy, the primary treatment modality on the unit, and 23 had not (attendance data were unavailable for 5 patients).

It is the policy of the inpatient service to use multiple diagnostic labels for the purpose of charting. Diagnostic labels for the 99 AMA patients included anxiety or depressive neurosis (N=65), psychotic disorders (N=17), alcohol or drug abuse (N=38), personality disorders (N=10), transient situational adjustment reactions (N=10), psychophysiological disorders (N=2), organic brain syndrome (N=2), and mental retardation (N=5). These diagnoses are comparable to those of our usual patient population, with the exception of a higher number of alcohol and drug abusers.

Data were collected from 33 female and 28 male AMA patients contacted by telephone 1 year after their discharges. There was a recidivism rate of 52.5% during the year after discharge. Previous studies had revealed recidivism rates of 20.9% and 26% for non-AMA patients (5, 6). Of those AMA patients who were rehospitalized, 73.5% returned to our service and 26.5% were admitted to psychiatric units in other hospitals.

Patients were asked if they were currently seeing someone for help on an outpatient basis; 21% refused to answer or were uncertain. Of those who answered the question, 62.5% were obtaining outpatient help. The two previous studies of non-AMA patients found rates of 54.8% and 61% for outpatient follow-up care (5, 6).

To determine the attitude of AMA patients toward our inpatient service one year after discharge, we asked whether they would be willing to return to the unit if it became necessary to do so: 52.5% answered yes, 14.8% said no, and 32.7% were uncertain.

Almost three-fourths (73%) of the patients thought that their condition had improved since discharge, 1% stated that they had remained the same, and 26% said that their condition had worsened.

The one-year follow-up data on AMA discharges seem to suggest that if patients are given the responsibility to choose the time of discharge, approximately 20% will elect to leave against the advice of their physician. We believed that hospitalization was initially indicated for all of these patients, and it was gratifying that over 50% of the AMA patients sought rehospitalization and that 62.5% of those who responded were engaged in outpatient follow-up care. It is interesting that of those patients who were rehospitalized during the year, 73.5% returned on a voluntary basis to the West Virginia University Hospital inpatient unit.

Our data do not support previously published claims that individuals discharged against medical advice have a posthospital adjustment similar to non-AMA discharges in that our AMA patients had a much higher recidivism rate. Outpatient follow-up treatment was approximately the same for our non-AMA patients and AMA patients.

We found a higher proportion of drug and alcohol abuse in our AMA patients compared with non-AMA patients, a finding that is consistent with previous reports (7, 8).

This study did not answer—and was not intended to answer—the question of whether AMA discharges are therapeutic. However, the data do raise several questions. Is the rather high AMA discharge rate a patient's way of determining whether or not he or she *is* in control of the treatment program? Do patients have to test our system to see if we are really sincere when we advise them that they have the responsibility for admission and discharge decisions as well as for making changes in their own behavior? One could propose this explanation in view of the fact that almost three-fourths of the AMA patients who were rehospitalized chose to return to our unit. One must also consider the possibility that the AMA discharge is an expression of anger and hostility, or even ambivalence, as some authors have suggested (8).

Many of the patients who leave our service against medical advice do eventually obtain psychiatric help either as inpatients or outpatients. Furthermore, it has been our impression, supported by the two previous one-year follow-up studies (5, 6), that giving patients the opportunity to play a significant part in admission and discharge decisions helps to establish a therapeutic inpatient milieu. Further evaluation of the effect of AMA discharges is needed.

Degraded Protein-Containing Food and Monoamine Oxidase Inhibitors

BY JULIAN LIEB, M.B., B.CH.

Although it is recognized that patients on monoamine oxidase inhibitors (MAOIs) should have some dietary restrictions, there is as yet no generally accepted diet. Reports by Horwitz and associates (1) in 1964 and Blackwell and associates (2) in 1967 that correlated hypertensive reactions in patients on MAOIs with the ingestion of tyramine-containing foods led to the development of MAOI diets that restrict these foods to a greater or lesser extent.

As early as 1909 Barger and Walpole (3), in a classical paper, reported the identification of isoamylamine as a "pressor constituent of putrid meat." In a recent report, Stewart (4) suggested that any protein-containing food that has undergone degradation could present a hazard to patients on MAOIs. This probably results from the fact that tyramine is produced by decarboxylation from tyrosine, which is derived from protein by proteolysis or hydrolysis.

I have recently observed 3 patients with hypertensive reactions in which the offending agent appears to have been denatured protein rather than the specific items that usually appear on MAOI diet lists.

Case Reports

Patient 1, a 48-year-old woman, was treated with 30 mg/day of tranylcypromine for a refractory bipolar depression. She reported a severe headache approximately 2 hours after eating a sandwich consisting of rye bread, butter, lettuce, and tuna fish from a tin that had been opened for 2 days and had not been refrigerated immediately after opening. Her blood pressure rose from a pretreatment level of 120/78 to 150/100 and subsided spontaneously over a period of 90 minutes. This patient experienced a second reaction some weeks later after drinking a cup of coffee with cream. Her blood pressure rose to 170/120, but she became normotensive within 30 minutes of oral administration of 50 mg of thioridazine.

Patient 2 is a 42-year-old schoolteacher who was treated with 60 mg/day of tranylcypromine for an atypical depression with prominent features of adult brain dysfunction. She reported a severe headache 1 hour after eating a cake-covered ice cream bar. The ice cream had been removed from the school refrigerator a few days previously and then returned to the freezer about an hour later. The patient stated that the inside of the freezer had a "peculiar, rancid smell." Her blood pressure rose to 160/115 from a pretreatment reading of 115/78 and normalized within 60 minutes without active treatment.

Patient 3 is a 57-year-old dentist who was treated with 30 mg/day tranylcypromine for a refractory bipolar depression. One hour after a lunch of beef chow mein he experienced a severe throbbing headache and had a blood pressure reading of 150/85 a half-hour later (pretreatment blood pressure was 110/70). He became normotensive within an hour and a half without active treatment. The chow mein consisted of bean sprouts, water chestnuts, ground beef, and soy sauce. The ground beef was prepared from a roast that had been cooked 3 days earlier.

Discussion

In case 1, the first reaction was probably due to previously opened canned fish and the second reaction to cream.[1] The reaction of patient 2 seems to have been due to rancid ice cream. In the third case the offending agent was either the beef or the soy sauce. Stewart (4)

Dr. Lieb is Assistant Clinical Professor of Psychiatry, Yale University School of Medicine, and Director, Dana Psychiatric Clinic, Yale-New Haven Hospital, 789 Howard Ave., New Haven, Conn. 06504.

[1]There was a report in 1959 of one patient who suffered "jitteriness" after drinking coffee while on an MAOI (5), but in view of the widespread consumption of coffee, it is highly unlikely that coffee is an offending agent.

reported that one sample of soy sauce was found to contain only 1.76 μg/g of tyramine and this figure, together with the paucity of reports of reactions to soy sauce, implies that an association is unlikely (4, 6). Stewart thinks that degraded protein in the meat seems a more likely explanation.

The four reactions reported in this paper lend support to Stewart's conclusion that the foods that have been reported to cause hypertensive reactions may have in common the degradation of a protein constituent, and that only fresh food or freshly prepared frozen or canned food should be eaten by patients on MAOIs (4).

Phenothiazine-Induced Priapism: A Case Report

BY JEROME I. GOTTLIEB, M.D., AND THOMAS LUSTBERG, M.D.

Priapism is defined as "the persistent abnormal erection of the penis, which usually occurs without sexual desire" (1). The condition is usually quite painful and often requires emergency urological procedures, such as draining and the use of shunts, to prevent permanent physiological impotence (2). It has been suggested that priapism can occur as a result of phenothiazine therapy (3). Although priapism secondary to the use of several different phenothiazines has been reported in the urological literature (3), we are aware of no such reports in the psychiatric literature.

The following case supports the concept of priapism as a complication of phenothiazine therapy. It is also the first report we know of that correlates priapism and mesoridazine therapy. In the discussion that follows, we will explore the physiological mechanism of phenothiazine-induced priapism.

Case Report

Mr. A, a 28-year-old chronic schizophrenic, reported a history of normal sexual functioning before July 1976. He had been treated intermittently over an 8-year period with chlorpromazine, 400–1000 mg q.d., with no known drug complications. In July 1976, the patient lost his job and moved to another city. He was taken off chlorpromazine and treated with mesoridazine, 400 mg q.d., for 3 months.

Three weeks after he started the mesoridazine, the patient had his first episode of priapism, which occurred after intercourse and resolved spontaneously within 12 hours. Following this incident, he reported having mild difficulties maintaining an erection, although he experienced no problems with ejaculation or orgasm.

On the day he was admitted to the hospital, the patient had taken approximately 1 g of mesoridazine. Several hours later he had had intercourse and had developed a painful and persistent erection, which eventually necessitated an emergency intracorporal shunt procedure. The operation was performed, but the patient became impotent, which led to a later psychiatric hospitalization for depression. (He was taken off mesoridazine.) At that time, he verbalized concerns about his impotence, loss of masculinity, and rejection by his girlfriend.

Mr. A had a history of multiple psychiatric hospitalizations for treatment of chronic schizophrenia and depression. He also had frequent concerns about his masculinity. In addition, he had a long history of drug abuse, including frequent use of cocaine, heroin, and amphetamines. He denied penile injections. His medical history is unremarkable, and laboratory studies revealed no evidence of hemoglobinopathies, platelet malfunction, or blood dyscrasias.

Discussion

The major tranquilizers have been implicated in several different drug complications related to sexual function. Theories involving various neurogenic pathways have been promulgated to explain impotence associated with antipsychotic medications. Before reviewing these, we will summarize current theories of the physiology of male sexual activity.

Psychic or local stimuli send impulses to the upper portion of the lumbar cord, where reflexes are set up. Parasympathetic outflow from S2-S4 then causes re-

When this work was done, Dr. Gottlieb was Chief Resident, Department of Psychiatry, Georgetown University Hospital, where Dr. Lustberg is Resident. Dr. Gottlieb is now in private practice at 8316 Arlington Blvd., Suite 516, Fairfax, Va. 22030; he is also Staff Psychiatrist at Fairfax Hospital and at the Woodburn Community Mental Health Center, Annandale, Va.

laxation of arterioles to the corpora of the penis. The cavernosus bodies are engorged under pressure, resulting in an erection. Sensory impulses from the glans penis then travel back to the sacral cord to the integrating center in the upper portion of the lumbar cord. These impulses subsequently trigger a sympathetic discharge that causes secretions from the seminal vesicles, ejaculatory ducts, and prostate. Somatic nerves from S2-S4 stimulate spasmodic contraction of muscles surrounding the urethra and pelvic floor, resulting in ejaculation. By stimulating contraction of the arterioles and relaxation of the venules of the penis, sympathetic nerves are responsible for detumescence (3, 4).

Phenothiazines have strong peripheral anticholinergic and adrenergic blockade properties. Failure to obtain or maintain an erection (under parasympathetic control) may result from the former. It has been postulated that alpha-adrenergic blockade may be responsible for retrograde ejaculation (5).

In priapism, two mechanisms may operate. First, by preventing the firing of sympathetic discharge, the phenothiazine-related alpha-adrenergic blockade may interfere with detumescence. Second, phenothiazines may have a contributing CNS effect (3). Hinman (6) postulated, for example, that prolonged stimulation of psychic centers may lead to continual venous stasis, which would increase the viscosity of the blood and result in subsequent edema of the trabeculae. Priapism would then occur and would be perpetuated by stimulation of a positive feedback system.

Thioridazine has been associated with sexual dysfunction (7), and chlorpromazine has been indicated as a possible etiological agent in priapism (9). In the case we have presented, the ingestion of 1 g of mesoridazine, a besylate salt of a thioridazine metabolite, was related temporally to the development of priapism. The possible mechanisms we have proposed warrant further investigation.

LETTERS TO THE EDITOR

This section contains reactions to Journal *articles, statements of opinion, comments on Association activities, requests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions regarding publication. Letters must be typed double-spaced throughout and should not contain more than 500 words and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for response. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform writers of the disposition of letters or return those which are not printed.*

Ethics in Alcoholism Research

SIR: I would like to express the considerable uneasiness I felt after reading "The Effect of Alcohol and Smoking on Testosterone Function and Aggression in Chronic Alcoholics," by Harold Persky, Ph.D., and associates (June 1977 issue).

The study they reported is of some slight interest, but the manner in which it was conducted is profoundly disturbing. I cannot help but bristle at the notion that a number of men who were addicted to alcohol were supplied with virtually unlimited quantities of that drug by physicians working in a public hospital with the support of the National Institute of Mental Health and the National Institutes of Health. There is nothing in the article to indicate that any attempt was made to direct these men toward help with their addiction. Granted that this was a research study, did the physicians involved in it make any effort to improve the health of their subjects? All of the subjects underwent a one-week period of enforced sobriety and abstinence from cigarettes. Were all of these men, regardless of their research or control group assignment, given the opportunity to continue that sobriety and abstinence *after* one week? I would contend that each of them should have been actively encouraged to do so.

I know this piece of research must have gotten past the appropriate "human rights in research" committee, but the article does not make it clear how that could have happened.

I hope that there are some explanations available. Otherwise, one must wonder what has happened to *primum non nocere*.

MARTIN GOLDBERG, M.D.
Philadelphia, Pa.

Dr. Persky and Associates Reply

SIR: We are clearly concerned about the welfare of alcoholic patients. In fact, two of us spend most of our time managing large treatment programs for addicted individuals. Furthermore, as noted in the paper, all of the volunteers were carefully screened, and those whose participation might involve medical or psychiatric risk were excluded. Excluded individuals were offered treatment and, of course, those accepted for the study were strongly urged to enter treatment after completion of the study. Treatment was both medical (for example, detection of unexpected diabetes or hypertension) and psychiatric. The patients were quite appreciative, and several maintained contact with the clinicians long after the conclusion of the study.

The study was not "gotten past" a human subjects committee. It was carefully reviewed by a committee at our university and by an independent committee at the hospital housing the research center. Both committees made helpful suggestions concerning the consent forms and determined that participation was of potential benefit to the subjects as well as to persons in general afflicted with this condition.

Dr. Goldberg seems to be upset primarily by the prospect of giving a drug to a subject under controlled conditions. This procedure is the only way that actual drug effects can be determined and has been generally accepted by the scientific and clinical community, as evidenced by the numerous publications describing studies of this nature over the past decade. We strongly feel that clinicians who are truly concerned about their patients will want to obtain valid information about the substances patients ingest. Information based on subjective impressions and historical recollection can be quite misleading. It is for this reason that studies of the present type are essential if we are to advance our understanding and treatment of addictive diseases.

More "Secondary Mania"?

SIR: I was interested in "Secondary Mania? A Case Report" by Kenneth N. Wiesert, M.D., and Hugh C. Hendrie, M.D., Ch.B. (Clinical and Research Report, August 1977 issue) because I have recently struggled with a similar case.

A 40-year-old married office worker was admitted to a community mental hospital two weeks after the birth of her first grandchild. The patient was referred from an emergency room where an interstitial pneumonia had been diagnosed. She was hyperactive, irritable, aggressive, and argumentative, with pressured speech. She said her husband was trying to poison her. She appeared drowsy at times, but this seemed secondary to her report that she had not slept for 3 days.

Her family said she had had two prior episodes of retarded depression, which had cleared without hospitalization. They said the patient also had episodes of hyperactivity and insomnia, during which she became restless and cleaned and

washed constantly. Her father had been hospitalized repeatedly for depression, and a sister and niece had been treated for retarded depressions.

After admission, the patient experienced the somatic delusion that she was in labor. However, delusions and insomnia cleared after 48 hours of treatment with lithium carbonate and haloperidol. She remained hyperactive, and was discharged with a diagnosis of bipolar affective disorder. The manic episode was felt to have been precipitated by a "grandmother reaction."

After her discharge, the following information was obtained. The patient had a severe akathisia secondary to haloperidol that complicated assessment of activity level. Two days before her admission, she had started a course of tetracycline. She had never taken this drug before, and it was discontinued on hospitalization. Before her admission and during the first few days of hospitalization, she experienced vivid waking dreams. In the hospital, she had been afraid to disclose this symptom. The previous "depressions" had coincided with two episodes of interstitial pneumonia.

She was withdrawn from psychotropics and continues to be followed by an internist. One year later, she manifests an obsessive-compulsive personality but functions well and has shown no mood swings.

It is difficult to say whether this is "secondary mania" or simply a difficult diagnostic situation. Two senior psychiatrists were convinced that this was a manic patient. Affective disorder, independent of a toxic precipitant, may eventually surface.

JEAN GOODWIN, M.D., M.P.H.
Albuquerque, N.M.

Structural Change in Tardive Dyskinesia

SIR: In regard to the "Special Section-Tardive Dyskinesia" (July 1977 issue) it seems to me there is a rather plausible explanation for the consistent finding that apomorphine does not worsen tardive dyskinesia, but amphetamine does. (I refer to the papers by Robert C. Smith, M.D., Ph.D., and associates; John W. Crayton, M.D., and associates; and Bernard J. Carroll, M.B., B.S., Ph.D., and associates.)

Since tardive dyskinesia occurs primarily with long-term antipsychotic drug use, it seems likely that it involves a structural change in the postsynaptic receptor, a change that does not reverse fully when the antipsychotic agent is withdrawn. This is supported by the fact that tardive dyskinesia occurs more often in elderly patients, since aging in general leads to decreased tissue plasticity and resiliency. This hypothesized structural change apparently makes the receptor more sensitive to dopamine (which is released by amphetamine) but less sensitive to apomorphine. It may originally be a compensatory change, i.e., an attempt by the neuron to circumvent the dopamine-blocking action of neuroleptics. It is not surprising that a structural change could affect which chemical moities would interact with and stimulate a receptor.

This theory of a structural change in the receptor causing tardive dyskinesia can be further evaluated by biochemical studies involving such dopamine agonists as piribedil and bromocriptine, but it can be verified only by histological techniques. One would speculate that any such structural change would occur in some but not all dopaminergic neurons, since dopamine receptors in different parts of the brain appear to be affected differently by long-term neuroleptic use (1–3). The occurrence of a structural change in the receptor seems to me a more likely explanation of why tardive dyskinesia does not worsen with apomorphine than does the explanation involving presynaptic receptors.

More on the Use of Manganese in Dyskinesia

SIR: We noted with interest the work of Richard A. Kunin, M.D., in the use of manganese in tardive dyskinesia (letter to the editor, January 1976 issue). We have had six patients with tardive dyskinesia who responded extremely well to 20 mg of manganese chelate t.i.d. The treatment seemed to work best in those who manifested fistulations of the tongue, with improvement of symptoms in 24 hours and remission within several days. Two of the patients stopped their medication either on their own or by error, and the dyskinesia symptoms recurred. Both patients again had remission of symptoms within several days after restarting the medication. Manganese chelate was also used with six other patients who had various extrapyramidal symptoms but no fistulations of the tongue, but none showed any improvement in the symptoms.

Ganser-like Signs in Carbon Monoxide Encephalopathy

SIR: The manifold array and fluctuating course of neuropsychiatric symptoms in carbon monoxide poisoning have been well described. Ginsburg and Romano (1) warned that "In particular the rapid changing of apraxias, agnosias, astasia-abasia, and the amnestic-confabulatory state often contributes to a false diagnosis of hysteria." Garland and Pearce (2) noted that "transient affective disorders of a depressive type were seen in the early stages." Many cases of carbon monoxide poisoning are results of suicide attempts, so misdiagnosis of depression may occur. Treatment with ECT may be harmful when there is brain damage by carbon monoxide.

We wish to report another potential diagnostic pitfall in cases of carbon monoxide intoxication: misinterpretation of signs resembling those of the Ganser state, classically described in prisoners awaiting trial (see reference 3 for a full description).

Our patient, a 20-year-old man awaiting trial, suffered smoke inhalation in a fire at the jail where he was being held.

Psychiatric consultation was requested 5 days after the fire because of his continued abnormalities of mental status. His gaze was vacant, his attention wandered, and speech was slurred. He answered only simple questions. He could identify a pen, watch, and key, count from 1 to 10 forward and backward, feed himself, and follow simple commands (e.g., to touch his hand to his nose). He stated he was in a hospital.

Seven days after the fire he called a pen a pencil and could not identify a watch or key. He counted from 1 to 10 but could not count backward, did not know where he was, and was unable to feed himself. Two days later he was unable to identify a pen or watch. He called a key a motor (it was a car key). He could write his name, but could not copy a circle or say what it was. He walked with agility and could follow directions as to when to return and where to sit. When asked whether he was right or left-handed, he answered, "both" (he is right-handed).

At that time, he gradually developed choreoathetoid movements and pseudobulbar speech. An EEG showed nonspecific generalized disorganization and slowing, and a CAT scan showed focal decrease in density in the region of the basal ganglia bilaterally. It is worth noting that as these signs developed, his perceptual and cognitive abilities began to improve. He is now gradually improving in all areas.

The variability in this man's mental status, with agnosia, apraxia, and "near-miss" answers, led us to consider the diagnosis of a Ganser state. However, as his course unfolded, evidence of his severe, multifocal brain injury became apparent. In cases of carbon monoxide encephalopathy, extreme caution is necessary before consideration is given to any alternative or additional diagnoses.

Death with Dignity and Survivor Guilt

SIR: I would like to present a clinical vignette that may illustrate the trauma which can result from the decision to permit discontinuation of extraordinary life-saving measures for one's parent.

A 40-year-old woman was recently brought to the emergency room for treatment of a self-inflicted gunshot wound to the right axilla. The bullet grazed the area of the brachial plexus, resulting in a paresis of the right upper extremity.

The patient reported that she was unaware of any precipitating factors that might have led to her decision to shoot herself. She seemed to be an articulate, intelligent woman and held a responsible position with a large department store. She stated that she had noted increasing feelings of depression for several months.

The interview revealed that in May 1977, the patient had been summoned to an intensive care unit in West Virginia, where her elderly mother had been sustained on a life support appartus for the preceding 9 days. The facts of her mother's case were clear, and attempts at resuscitation were futile. After consideration of the evidence, the patient signed a document authorizing the hospital staff to discontinue use of the life-support equipment.

Although great strides have been made in obtaining death with dignity for the hopelessly ill, the assumption is often made that the ancient struggle against the wish for the parent's death has dissolved. The burden may be even greater for the obsessional patient who has masked his or her affect behind an overdetermined rational exterior. We must realize the potential for guilt in a person who has acted out his most feared impulse: homicide.

Silver Spring, Md.

More on Drug-Induced Blurred Vision

SIR: I concur with the observations about blurred vision and its treatment with pilocarpine made by J. Gary Carter, M.D., and associates (letter to the editor, August 1977 issue). I have encountered this problem in a small number of patients I have treated over the years with phenothiazines, tricyclic antidepressants, MAO inhibitors, and butryophenones. This complication has occurred in about 10%–20% of 321 patients with Gilles de la Tourette's syndrome who were treated with varying dosages of haloperidol. The effect is dosage-related but may occur with small dosages. Although the problem usually disappears within 6 to 12 months, it is very distressing to patients who are students, accountants, jewelers, etc.

An alternative to the use of daily pilocarpine that has been effective for most of our patients is the prescription of inexpensive and temporary corrective lenses that can be discarded when the complication disappears.

ARTHUR K. SHAPIRO, M.D.
New York, N.Y.

Another Approach to Self-Induced Depersonalization

SIR: The potential ill-effects of popular techniques for inducing altered states of consciousness (ASCs) have been recognized longer than was implied by Raymond B. Kennedy, Jr., M.D., in "Self-Induced Depersonalization Syndrome" (November 1976 issue). Dr. Kennedy was correct to complain of the limited interest the Western psychiatric literature has shown in these phenomena. However, the varieties of psychological disturbance that may be caused by naïve abuse of consciousness-altering techniques are more extensive than his title suggests.

A wide range of techniques (including both spiritual and "commercial" meditation, hypnosis, autogenic training, Zen, Yoga, and states induced by various drugs, prayer, fasting, reverie, and sensory deprivation) have been used to induce similar states, and all have the potential to produce negative as well as positive effects (1).

Zen recognizes such effects as *makyo* and *Zen-byo* (Zen-illness). Zen aims at a full enlightenment and awakening of the personality, but this state of *satori* is different and more humble and realistic than the delusory self-induced trance-states and depersonalization/derealization states known as *makyo*. Disciples are taught that they have to pass through a

sequence of major and minor *satoris*, each representing the integration of emerging subconscious material into the personality. Over-valuation of and attachment to a small *satori* is *makyo*.

Psychotic symptoms, megalomaniacal and omnipotent delusions, aggression, and even suicide are recognized as occasional complications of the *makyo* state in Eastern literature (1). A recent case report (2) described a middle-aged woman who developed a severe dysphoric episode after initiation into Transcendental Meditation. Takaishi and others (cited in reference 1) have described disturbances in Japanese high school students who had "played" with hypnosis, including difficulty awakening from trance, continuation of daydreaming, and unreality states.

Meditation involves a temporary inhibition of conscious ideation. This can allow the release of unconscious and otherwise repressed material that should be mildly observed and not identified with or cathected. The naïve and inadequately trained meditator may fail to distinguish between the consciousness/self who perceives and the conscious ideas that are perceived, mistaking a part of the experience for the actual goal of psychotherapy or meditation.

While meditation techniques can be of considerable personal and clinical value, their indiscriminate merchandising, which has been a notable feature of the "consciousness movement," has significant risks. There should be some selectivity with regard to those who are trained in such techniques, since an appropriate degree of ego strength is needed. Individuals with hysterical personalities may be more prone to develop a dissociative state in relation to an ASC, and those with borderline states may also find ASCs disturbing. Education about the goals and effects of the techniques and guidance with regard to the nature and management of such experiences as *makyo* would make the experience safer.

Dr. Kennedy described how reassurance transformed frightening depersonalization into ego-syntonic occurrences and proposed that patients in this condition should be taught to accept themselves and their depersonalization uncritically. It is important not to encourage cathexis of the experiences or overidentification with them. The Zen technique for dealing with *makyo* is to stay indifferent to the phenomena, recognizing them as products of the ego/self but merely observing them neutrally, not considering them as real. Other techniques such as concentration on breathing or posture have also been used, and simple autogenic and muscle-relaxation routines can be useful.

MICHAEL A. SIMPSON, M.D.
London, England

Dr. Kennedy Replies

SIR: I did not mean to imply that such states as depersonalization are to be cathected, which seems to be Dr. Simpson's understanding of my article. He is quite right to emphasize that these phenomena should be transitory. In the cases reported, one person was simply instructed to discontinue meditation and the other was referred (not by myself) to the Indian Guru Swami Muktanada Paramahansa, a man with considerable knowledge of such situations.

Further, I did not mean to imply that my report of such situations was unique. The world literature on metaphysics and allied fields including meditation is replete with such topics, far too numerous to mention, many of which antedate the birth of Christ. The psychiatric literature is less well endowed, however, and one hopes the in-press reference cited by Dr. Simpson will add to the psychiatric literature on such subjects.

I wish to add one caveat in reference to Dr. Simpson's letter, however. He has used several terms that are not a part of the psychiatric terminology and that remain quite subjective and largely theoretical for me—and I suspect for most people who have done work in such areas. Such subjective terms as *satori* and *makyo* occupy an appropriate place in religious and metaphysical writings but do not seem to me to have a legitimate place in Western psychiatry, which is already plagued with the struggle to develop a scientific terminology that will allow us to approach a relative form of objectivity. A precise language is the basis for any reasonable scientific endeavor, and the Russian mystic and metaphysician Peter Ouspensky (1, 2) designated this as one of the cornerstones in any sound metaphysical system designed to study consciousness. Ouspensky also notes that such precise languages are precise only for the time and place of the particular system with which they are used and are not transposable. As scientists, we would do well to heed such advice lest we create (or add to) our own Tower of Babel.

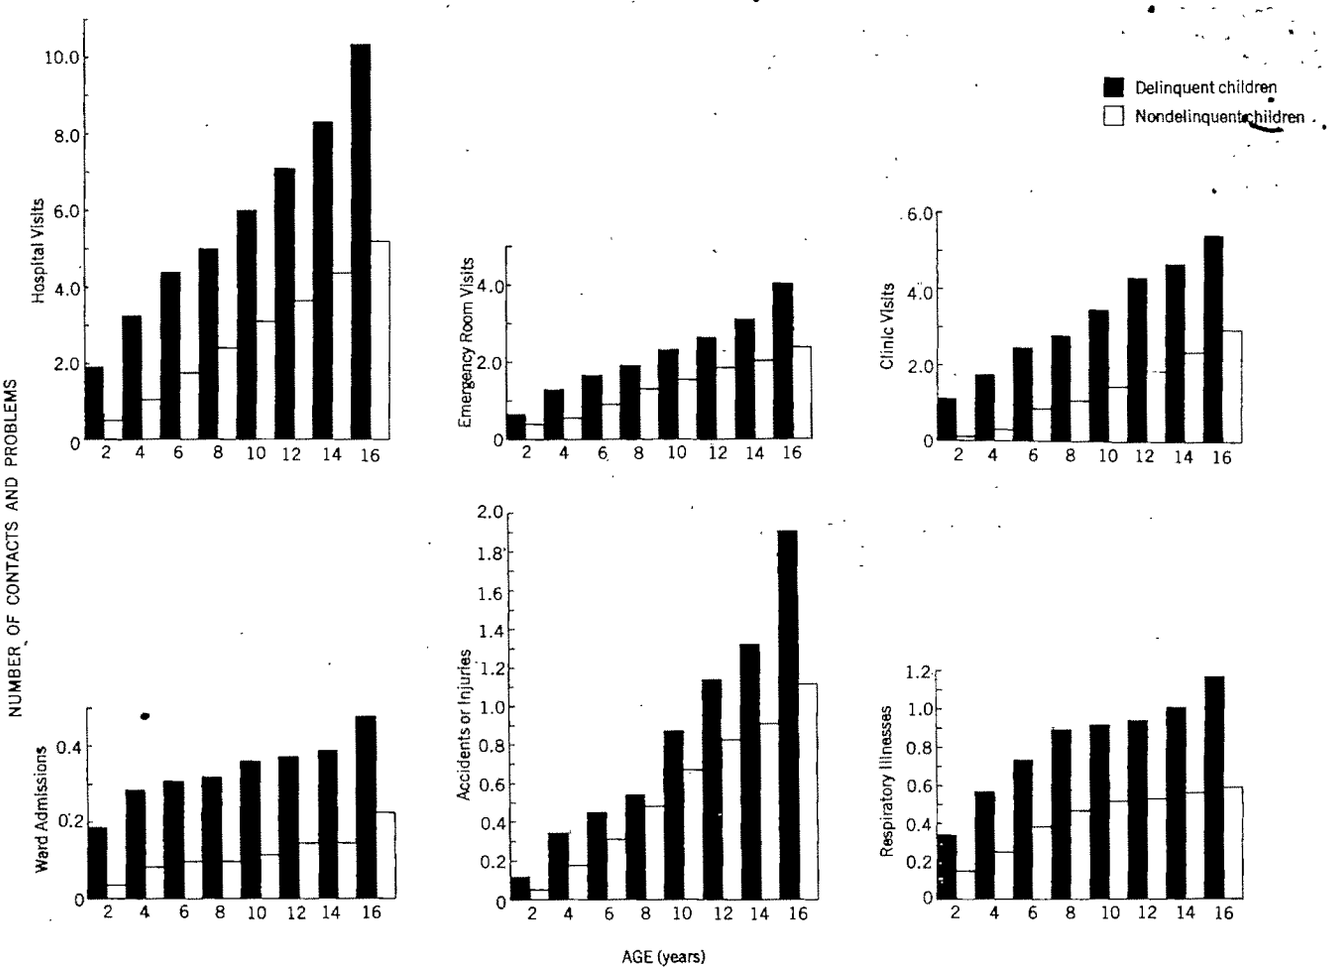
RAYMOND B. KENNEDY, M.D.
Dallas, Tex.



Psychiatrists in CMHCs

SIR: I have just completed a period as medical director of an urban community mental health center with a catchment area of 200,000 people (predominantly blue-collar workers and their families). I feel compelled to respond to the excellent article by James S. Eaton, Jr., M.D., and Leonard S. Goldstein, M.D., "Psychiatry in Crisis" (June 1977 issue).

I believe that one of the reasons why the number of psychiatrists serving in community mental health centers has decreased in recent years is that mental health administrators—most of them nonphysicians—seem to feel that nonphysician members of the mental health team can do the job of therapy just as well or better than psychiatrists and do it for less money. Therefore, from a cost-efficiency standpoint, it seems to such administrators more logical to hire less expensive mental health professionals rather than "high-priced" psychiatrists.

The potential fallacy of this kind of administrative thinking becomes apparent only in the long run (if ever), and through the results obtained, in terms of the importance of accurate

BOOK REVIEWS

You Are Not Alone: Understanding and Dealing with Mental Illness. A Guide for Patients, Families, Doctors and Other Professionals, *by Clara Claiborne Park with Leon N. Shapiro, M.D. Boston, Mass., Atlantic-Little, Brown, 1976, 480 pp., $15.00.*

This sizable volume was four years in the making and was written to tell the readers what they need to know about mental illnesses and the problems of living that usually bring people to mental health services. Ms. Park is a dedicated woman who has known the frustrations of seeking help for an ill child and who is now intent on helping people who do not know what to do or where to go when a loved one becomes ill, and Dr. Shapiro is a knowledgeable psychiatrist. Ms. Park learned from "unexpected people in unexpected places what you can do especially when you realize that you are not alone"; therefore, this is the central theme of the book. She found that the mind has many mansions and that the way we see the world is not the only way it can be seen.

The authors are aware of and have looked into every controversy and every advance in the mental health field. Their stated intent is simply to present both sides of the disagreements about controversial subjects, to do this fairly, and to do it in sufficient detail. They introduce various specialists in the mental health field and describe the background, pedigree, and functions of each. They discuss the labeling of illnesses, medical terms, and the medical model. They list various opinions of mental illness and give lucid discussions of all types of illnesses that mental health workers encounter. These are informed, detailed discussions, as are the listings of the various forms of treatment—from the analytic systems of Freud, Jung, and Adler to the newer therapies, including even the radical therapies, which they say "challenge all forms of treatment and find everybody out of step but the patient." This suggests to them "not psychiatry but anti-psychiatry."

The authors explore dynamic therapies, behavior therapies, and group therapies. They posit the reassuring thought that most psychotherapies are more different in theory than they are in practice. "Dynamic or insight therapy," they note, "works to change behavior from the inside out and behavior therapy works from the outside in." They doubt that insight and understanding into the sources of psychological problems in themselves have the power to change things. Self-knowledge, they say, is no guarantee whatever of effective problem solving and may not even be necessary to it.

Wittingly or unwittingly, the authors lean toward the behavioral approach, noting that many of its patients are not of the YAVIS[1] variety; rather, they are often the direct opposite. They feel that because the system is based on fundamental principles of learning behavior it works for everyone—the chronically insane, the brain damaged, the neurotic, and the delinquent.

Somatic treatments are discussed fairly and intelligently—lithium, ECT, and orthomolecular therapy all come under the authors' ken. There is a broad discussion titled "Thinking About Causes" in which the authors range far and wide. They apparently have read everything; their footnotes are as voluminous as their bibliography.

This work reminds us plaintively of the pain caused by the assumption of family blame for a member's illness before all of the facts have been considered. However, the authors view the search for causes of mental upset as important for everyone and delve into these as well.

The second section of the book is concerned with the practical matter of what the community can offer. The search sometimes is disheartening, and the guiding theme the authors offer is never to accept no for an answer: "Go to the real people," they say, i.e., those who know where and how help can be found. They point out that under some circumstances the home can be a therapeutic milieu and families can be cotherapists. The authors bring home to us sharply the burden on the family of dealing with sick loved ones. Frequently the tolerance of the family is high because of interest and guilt feelings about the patient's illness.

Hospitals of various types, "The Law and Your Relative," and various areas of conflict are all sympathetically considered. Part three of the book is titled Outrage—And How to Use It. Much of it is concerned with the hunt for proper placement of children in need of help in the face of bureaucratic school officials. The authors also consider the stress of dealing with the elderly who are mentally ill. The essence of the final chapter, "The Lord Helps Those Who Help Themselves," is that one can get any kind of help needed if he or she is persistent.

If this review seems pedestrian, it should not be, for I enjoyed this as the most complete book of its kind that I have yet encountered. Mind you, there is much I disagree with in it, but that does not subtract from the fact that it is an excellent work. It is well written, moves along smoothly, and there are sprightly little quips in the margins. Appendix A suggests some helpful readings, and Appendix B gives some useful addresses, ranging from that of the American Psychoanalytic Association to that of the *Madness Network News*, with various stops in between. There is no doubt about the fact that all of this information will be of invaluable assistance to families of sick persons—and for doctors, too; I picked up a great deal of information from it myself.

[1]YAVIS is an acronym for ideal patients for insight therapy—Young, Attractive, Verbal, Intelligent, and Successful (1).

F.J.B.

An Assessment of the Community Mental Health Movement, *edited by Walter E. Barton and Charlotte J. Sanborn. Lexington, Mass., Lexington Books (D.C. Heath and Co.), 1977, 191 pp., $18.50.*

In view of the attention now being paid to the community mental health centers program as a result of the need to recommend changes that might lead to Congressional action and the ongoing activity of the President's Commission on Mental Health, this collection of papers edited by Drs. Barton and Sanborn is timely and informative to those with interest in this area. The publication is the product of a three-day institute held at Dartmouth College in Hanover, N.H., in September 1975. Although editing has delayed its publication until 1977, this does not detract from the value of the papers presented in this volume.

The initial chapters by Drs. David Musto and Jack Ewalt are particularly helpful, not only because they provide a historical context for an assessment of the community mental health center program in its current operational form but also because they correct some of the current mistaken perceptions regarding the original intent of the first Joint Commission on Mental Illness and Health (1955–1960). These chapters also emphasize the importance of understanding the historical perspective before considering major changes in philosophy or programming. An excellent example is provided by Dr. Ewalt in his review of the actions of the first Commission regarding prevention services. With the current thrust toward examining the relationship between direct services and primary prevention services, with a possible interest in shifting the balance toward primary prevention, his words of caution are important.

The papers of Drs. Jack Zusman and Donald Langsley provide an excellent discussion of the philosophical basis of community and social psychiatry, a thorough review of the multiple components of the community mental health center program, and an excellent bibliography that will enable any interested reader to explore additional sources.

The three papers by Drs. Jack Wilder, George Dyck, and Elmer Gardner are concerned with a broad overview of different operational community mental health center programs. Drs. Wilder and Gardner give examples of urban community mental health center programs, and Dr. Dyck provides a description of rural community mental health center programs. Dr. Bernard Holland gives a brief but excellent assessment of the criticisms of community mental health centers. Each of these chapters is lucidly written and highlights the major issues.

Finally, the concluding chapters by Drs. Lucy Ozarin and Stanley Yolles review the available evaluation literature on community mental health center programs and make a few predictions regarding the future directions in which the community mental health center will have to proceed to gain stability.

My only criticism of the papers in this volume is that, although they provide an excellent description of the history of the community mental health movement and its current operational mechanisms, they offer very little concrete information that will assist interested individuals in defining workable solutions to address the problems presented. Nevertheless, this volume is an excellent addition to the existing literature on community mental health, primarily because of its scope and lucidity.

ALLAN BEIGEL, M.D.
Tucson, Ariz.

Psychological Problems of the Child and His Family, *edited by Paul D. Steinhauer and Quentin Rae-Grant. Toronto, Ont., Canada, MacMillan of Canada, 1977, 449 pp., $12.95.*

Those of us who have tried to teach growth and development and psychopathology of childhood and adolescence to medical students face the difficulty of trying to reach a large, diverse audience. Some students have a background in psychology; others have neglected the social and behavioral sciences while concentrating on gaining admission to medical school. Some could not care less about the subject; others, whose interest is awakened, demand more. Some understand the significance of psychological factors for medical practice; others are interested only in the "blood and guts" of medicine. The design of an appropriate textbook for this conglomerate audience has confounded all of us.

In *Psychological Problems of the Child and His Family*, our Canadian colleagues have added to the array of volumes in this field a compendium of discussions of the basic and significant areas produced by various authors. Each chapter constitutes a lecture in itself and is accompanied by a bibliography. The writing is interesting, simplified, and thorough. Although a reader may carp unnecessarily at the selection of references or the underemphasis on certain areas of development, he or she will find here a relatively brief text that often oversimplifies the complex but never insults the audience.

Texts written by a number of authors are often a patchwork with an unevenness of quality. The editors of this book have painstakingly reviewed each chapter so that the text reads as if it were done by one or a very few authors. It is free of jargon. There are many illustrative vignettes. Some chapters are, of course, better than others, but this is a minor criticism. Emphasis is placed on interpersonal aspects without neglect of intrapsychic and developmental aspects. No one attitude is overemphasized, and no one rides a particular hobbyhorse. For example, the admonitions regarding the limitations and misuse of drug therapy are appropriate. The role of the physician in family crisis and chronic care is well presented.

Anyone teaching a course in child psychiatry to medical students (there are precious few who do, since curriculum time is avidly guarded and the priority assigned is low) will find it useful to peruse this text. The authors state in the preface, "If it is to succeed in its task, it is not enough that it be read and memorized; it must be understood and even enjoyed." It has succeeded in its task. It is my hope that many of our students will sip its contents; it is a good vintage.

IRVING PHILIPS, M.D.
San Francisco, Calif.

Temperament and Development, *by Alexander Thomas, M.D., and Stella Chess, M.D. New York, N.Y., Brunner/Mazel, 1977, 265 pp., $13.50.*

Clearly, the brightest lights in terms of serious research in personality development are Thomas and Chess, who initiated the New York Longitudinal Study some 20 years ago. Their work has produced two widely acclaimed publications, *Behavioral Individuality in Early Childhood* (1) and *Temperament and Behavior Disorders in Children* (2). With this third publication one finds a fuller exposition and perhaps a greater emphasis on the amalgam of constitution and environment.

The three temperamental types teased out of their studies are familiar to all: the difficult child, who reacts strongly and negatively, is slow to adapt, and is irregular in habits; the easy child, every parent's fondest wish, who is very adaptable, positive in outlook, and very regular; and, lastly, the slow-to-warm-up child, who, although not negative, approaches new situations cautiously but in the end positively if not pushed too hard. The authors include short questionnaires on temperament for parents of infants and parents and teachers of children 3–7 years of age. Although such questionnaires are somewhat gimmicky, their purpose is important—to assist in identifying the child's basic temperament. Once temperament has been identified, the authors feel that there will be a degree of predictability in terms of the child's response to stressful demands in the environment.

The authors feel that their 20 years of investigation support their basic contention that it is possible to identify in infancy children who will be at risk in terms of their basic temperament and future behavioral disabilities. They include many practical suggestions for parents who have identified their child's temperament; e.g., a slow-to-warm-up child should be given extra time to adjust to such new situations as school and camp.

There is a most interesting appendix on conducting an interview on the child's everyday behavior. It is a personal communication to the authors from Dr. P. Graham, who with Rutler and George has also studied temperament as a predictor of behavior disorders in children. Their studies attempt to describe the child's personality dimensions as mood, intensity of emotional expression, activity, fastidiousness, malleability, regularity, and approach/withdrawal behavior.

Thomas and Chess conclude their book with a quotation from Sir Thomas Browne:

> It is the common wonder of all men, how among so many millions of faces, there should be none alike: now contrary, I wonder as much how there should be any. He that shall consider how many thousand several words have been carelessly and without study composed out of 24 letters; withal how many hundred lines there are to be drawn in the Fabrick of one man, shall find that this variety is necessary.

This is an important study; this is an important book.

The Symbolic Life: Miscellaneous Writings. The Collected Works of C.G. Jung, Vol. 18. Bollingen Series XX, *by C.G. Jung; translated by R.F.C. Hull. Princeton, N.J., Princeton University Press, 1976, 852 pp., $22.50.*

We now have the final volume of Jung's *Collected Works*. All that remain are the two volumes of general bibliography and general index. No library of any significance should be without this 22-volume series.

Psychotherapists, analysts, scholars of psychoanalysis, and analytical psychologists may profitably turn to volume 18 in the series. It is difficult to review a collection of 160 disparate items written by Jung over a period of 60 years—a mélange of addresses, reviews, forewords, letters, questions and answers, comments to newspapers, comments to magazines, unpublished manuscripts, and other writings. The title of the book is misleading, but its subtitle is not. The title comes from Jung's statement, "You see, man is in need of a symbolic life—badly in need. . . . Where do we live symbolically? Nowhere, except where we participate in the ritual of life" (p. 273). This statement is from his 1939 address to the Guild of Pastoral Psychology in London.

The volume consists of 16 parts; the last 13 are titled according to the volume of the collected works to which they are, in effect, supplements. With this in mind, the reader can understand why things were divided up in such a way. Many of the contributions came to light only after the previous volumes had been published. The 16 sections are titled as follows: The Tavistock Lectures (1935), Symbols and the Interpretation of Dreams (1961), The Symbolic Life (1939), On Occultism (volume 1 of the *Collected Works*), The Psychogenesis of Mental Disease (volume 3), Freud and Psychoanalysis (volume 4), On Symbolism (volume 5), Two Essays on Analytical Psychology (volume 7), The Structure and Dynamics of the Psyche (volume 8), The Archetypes and the Collective Unconscious (volume 9), Civilization in Transition (volume 10), Psychology and Religion (volume 11), Alchemical Studies (volumes 12, 13, and 14), The Spirit in Man, Art and Literature (volume 15), The Practice of Psychotherapy (volume 16), and The Development of Personality (volume 17). Although these items would obviously interest, amaze, delight, or provoke individuals differently, I will highlight the items that impressed me.

My general reaction to this book is a reflection of a statement taken from Jung's foreword to Harding's book *Psychic Energy* and reprinted in this volume:

> The pioneer in a new field rarely has the good fortune to be able to draw valid conclusions from his total experience. The efforts and struggles, the doubts and uncertainties of his voyage of discovery have penetrated his marrow too deeply to allow him the perspective and clarity of vision needed for a comprehensive survey. Those of the second generation, who base their work on the groping experiments, the lucky hits, the circuitous approaches, the half truths and mistakes of the pioneer, are less burdened and can take more direct roads, envisage more distant goals. (p. 469)

The inclusion of Jung's prefaces to the books of his students and analysands in this final volume of his writings is doubly germane. These prefaces, reviews, and forewords reveal the insight of the pioneer into the products of the second generation and vice versa. The volume is a kind of springboard to us of the third generation, as Jung notes, "This simplification and clarification redound to the benefit of those of the third generation, who are thus equipped from the outset with an over-all chart."

The five Tavistock lectures, which Jung gave in 1935 at the age of 64, are informative, spirited talks presenting an overview of analytical or complex psychology, the basic ideas of the collective unconscious, association test experiments, typology, dream analysis, and transference. The question

and answer periods following each speech reveal an amplification of Jung's ideas as well as his personality. (The lectures have been published before [1]). Jung's detailed interpretation of one dream (lecture 5) is a precise example of the "Jungian" analyst at work.

The chapters in the section titled Symbols and the Interpretation of Dreams should especially be noted: "The Significance of Dreams," "The Function of the Unconscious," "The Language of Dreams," "The Archetype in Dream Symbolism," and "The Problem of Types in Dream Interpretation."

Since some people tend to confuse Jung with his subject, especially when he deals with occultism and the mystic quality of the archetypal experience, the section on occultism, which contains his original views on clairvoyance, magnetic phenomena, visions, spiritualism, apparitions, ghosts, and what these phenomena signify, gives us the chance to examine what Jung actually said and the context in which he said it.

The previously unpublished typescript of a 1916 lecture titled "Adaptation, Individuation, Collectivity," presented in Zurich, contains trenchant observations of the psychology and ethics of work and individuation.

In the 88-page section titled Civilization in Transition, Jung expresses his personal and symbolic ideas about the world in which he lived—comments on Switzerland, Germany, Europe, America, Communism, and National Socialism. Jung's feelings about civilization are particularly expressed in the memorable essays "Return to the Simple Life," "Marginalia on Contemporary Events," "Answers to 'Mishmar' on Adolph Hitler," and "Psychology and National Problems."

The section titled Psychology and Religion includes the noteworthy chapters "Jung and Religious Belief" and "On the Discourses of the Buddha." Jung's clinical, symbolic ideas will always annoy individuals who insist on intellectual answers and theories, who see them as poetic, mystic, and unscientific, but what is true? To the phenomenologist/empiricist Jung, psychic entities are truths. He asks, correctly, not are they true (we have long since passed that step with mythology), but who says they are true, in what psychological situation, and what is the symbolic meaning.

The Symbolic Life may turn out to be Jung's last symbolic gift to a world badly in need of the symbolic life:

> That gives peace, when people feel they are living the symbolic life, that they are actors in the divine drama. That gives the only meaning to human life; everything else is banal and you can dismiss it. A career, producing of children, are all *maya* compared with that one thing, that your life is meaningful. (p. 275)

In conclusion, I again quote Jung: "I can recommend [this book] to all those who know how to value things that break through the monotony of daily life with salutary effects [sometimes!] shaking our certitudes and lending wings to imagination" (p. 327).

Primate Models of Human Neurogenic Disorders, *by V. G. Startsev; translated by Marienne Schweinler and Vadim Pahn; edited by Douglas M. Bowden. Hillsdale, N.J., Lawrence Erlbaum Associates (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1976, 191 pp., $19.95.*

The aims of this book are to present to the medical world the development of a different kind of experimental model of neuroses in monkeys and to acquaint American scientists with the work of Soviet primatologists. It deals both experimentally and theoretically with the question of symptom specificity, that is, why some individuals respond to psychological stresses with gastric disorders, others with sexual impotence, and still others with high blood pressure.

The book reports a series of studies by Russian workers involving the following conditions: 1) gastric achylia, 2) precancerous gastric lesions, 3) functional hyperkinesis and paralysis, 4) experimental neurogenic disorders of the sexual cycle, and 5) chronic hyperglycemia.

This is a very interesting book. I highly recommend it to interested American scientists as an overview of what the Russians are doing in the area of primate research, particularly as it involves modeling of human "neurogenic" disorders. The terminology throughout the book will be confusing to most American readers without a careful study of the editor's introduction; however, this introduction is well done and will clarify otherwise confusing terminology.

The basic model described in a number of sections throughout the book relates to immobilization stress, involving the concept that the physiological system likely to become chronically disturbed is the one that was particularly active when the animal was subjected to the nervous stress. This model is discussed in relation to the systems listed above. Many readers will be frustrated by the lack of detailed reporting of studies. Throughout the book, one finds jumps from the theoretical background of the study to the conclusions without adequate descriptions of the methodology and, especially, of the data.

The preface by David Graham is well written. There is increasing interest in primate models, and, although this book represents one approach among many, it is worth having because much of the work described is not easily available elsewhere.

WILLIAM T. MCKINNEY, JR., M.D.
Madison, Wis.

Physical and Sexual Abuse of Children: Causes and Treatment, *by David R. Walters. Bloomington, Ind., Indiana University Press, 1975, 188 pp., $7.95.*

With minimal attention to the gory characteristics of child abuse, the author, a psychologist, presents a timely overview of the subject for professionals involved in treatment of the problem. The difficulty inherent in specifying behaviors that constitute abuse remains unsolved. However, the author differentiates between the physical and sexual abuse of children in both etiology and treatment. Perhaps one of the most helpful sections of the book is Walters' typology of physically abusive adults. Among the 10 classifications of abusers are the parentally incompetent, the frustrated and displaced, the accidental or unknowing, the institutionally prescribed, and the subcultural.

According to the author, effective treatment of the child abuser is contingent on differential diagnosis as to type of

abuser. The immediate treatment goal for all types is cessation of the abuse by assisting the parents in the development of nonabusive child-rearing techniques. Our traditional view of the child abuser as mentally ill should be discarded, Walters says, because pathology per se is present in only a minority of cases. However, when the abuse is a symptom of mental illness, removal of the child from the home is more often indicated than in other types. Prognosis is poor for the mentally ill abuser because cessation of the abuse is dependent on resolution of the illness. Walters emphasizes that no therapeutic reasons justify risking the life or well-being of a child and that it is unethical to use a child as a clinical tool to aid the mentally ill abuser.

Sexual abuse of children typically involves an adult male and a female child. However, the sexual taboos of our society have severely hampered our understanding and treatment of the problem, and reporting of such cases is limited by the fact that the abuser is usually a friend or member of the child's family. Our society's approach to sexual abuse is unique in that the child frequently becomes the accused while the adult is viewed as the victim. The author believes that the dynamic underlying sexual involvement with one's own child is anger toward one's spouse. He considers effective treatment of the sexually abusive adult extremely difficult and recommends referral to a mental health professional.

Although some of the strategies outlined by Walters for the amelioration of child abuse seem rather obscure, his suggestions for treatment are noteworthy. Group therapy is recommended as a more effective and less costly treatment approach than individual therapy. Regardless of treatment modality, a nonjudgmental and nonauthoritarian attitude is required of the therapist if change is to occur. This book is highly recommended for professionals involved in the problem of child abuse.

CLAYTON PETTIPIECE, M.D.
Omaha, Neb.

The Measurement of Personality, *edited by H. J. Eysenck, Ph.D., D.Sc. Baltimore, Md., University Park Press, 1976, 511 pp., $29.50*

Dr. Eysenck presents a trait-oriented conceptualization of personality and an essentially norm-centered strategy for comparing differences between people. There is nothing new about this; it is offered partially to strike a blow against person-oriented conceptualizations, which, along with being too "literary" for Dr. Eysenck, give evidence that people do not manifest traits consistently. Although one admires Dr. Eysenck's strong personal convictions about his work, his view of his scientific approach as strong, as compared with phenomenological approaches as weak, is an oversimplification that ignores the tremendous complexity of human nature. It is no more meaningful than calling Rousseau a man of large vision and Eysenck a man of small vision.

In *The Measurement of Personality* Dr. Eysenck divides 67 research articles into 10 sections. He prefaces each section with a commentary aimed at forging a rudimentary paradigm he believes is emerging for the field of personality. The linking commentary may be compared to a theoretical lightning-and-thunder bonding together of a string of molecules and stirring them with vitality. Dr. Eysenck restricts his conceptualization of personality to an elementary set of factors, such as traits, which he believes underlie individual differences. For a trait to warrant inclusion into his matrix it must be able to be integrated into general psychology (perception, learning, etc.), must be anchored biologically, and must be strongly determined by genetic causes.

According to Dr. Eysenck, "A proper system of description of human personality would resemble the Mendelieff table of the elements." He believes that at present only three elements outside the cognitive field present themselves as candidates: extroversion-introversion, neuroticism or emotionality as opposed to stability, and psychoticism. (I am reminded of the research and writings of Roland Fischer, who offered a cartography of inner space to match our detailed maps of outer space [1].) Dividing people into extroverts and introverts (using the Myers-Briggs Type Indicator) and comparing them along various dimensions of perception, the extrovert is less sensitive to taste and less drug-sensitive. He or she is described as requiring more sensation and given to thinking and judging, whereas the introvert is more intuitive and given to feeling and perceiving, is taste-sensitive, and requires a lower effective drug dosage.

The Measurement of Personality throws into bas-relief the physiological bases of Eysenck's theory of personality dimensions along measures of sensation, vigilance, perception, psychomotor behavior, learning and conditioning, memory and recall, cognition and creativity, and social and sexual behavior. He makes the point that individual psychological experience is tied in predictable ways to traits correlated to physiological factors. He presents a great deal of substantial evidence for this point. Nevertheless, he is inclined to fault descriptions of personal experience that do not address themselves to biological issues. Perhaps, as his evidence suggests, there are two kinds of people in the world along the extrovert (sensor, judge) and introvert (intuitor, perceiver) continuum that give rise to two difficult approaches to personality study. It seems that there are ways of accepting this phenomenon without thinking of one approach as hard and strong and the other as soft and weak.

DAVID F. BERRY, PH.D.
West Hartford, Conn.

Suicidology: Contemporary Developments, *edited by Edwin S. Shneidman, Ph.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1976, 546 pp., $26.50.*

This book by a variety of knowledgeable authors covers many dimensions of suicide and related topics. The very structure of the book offers a unique touch in that each chapter is preceded by a historical note or excerpt. The first one, encompassing the sections on suicide from the *Encyclopedia Britannica* of 1910–1911 and that of 1973, includes Shneidman's own minimasterpiece.

Nonetheless, *Suicidology* is a book of mixed merit. Perhaps it represents a stage in evolution of the understanding of a subject. An early stage of applied knowledge is the collation of information and the creation of generalizations that act as guidelines. As sophistication increases and nuances become more appropriate, one sees the development of differentiation and the breakdown of generalization. Thus this

book demonstrates new perspectives while it mandates a questioning of traditional viewpoints.

The literary qualities of the book work to its disadvantage as a communications device. Many chapters are written in a heavy-handed style that requires the utmost in concentration; this is not a book to read during the 10-minute break. In some cases, statistics abound to befuddle the perusing reader; in others, one encounters numerous examples of specialized vocabulary and almost idiosyncratic verbalisms and neologisms.

With its defects, this book is much better than most edited books; it is replete with reams of information, controversy, and even philosophy (e.g., will suicide become the preferred way of death?). The chapter on Great Britain would imply that the Samaritan Suicide Prevention Movement has lowered the suicide rate there in contrast to its apparent results in the United States.

One encounters the effect of fluidity of time and social change in relation to suicide. According to some measurements, suicide has decreased over the decades. Young suicide shows an increase, as does black suicide; young blacks and whites in the New York area have about the same suicide rate. However, current sociological studies offer contradictory or limited interpretive opportunities.

Predictability remains an unachievable goal. Diggory states, "Our present knowledge is all hindsight; there is no method of predicting." Kiev offers a mass of clinical observations, particularly of the difficulties in handling impulsive people and those who deny the sick role; he states that the social world of the patient is more critical in the patient's subsequent clinical course than diagnosis or severity of the psychiatric condition. The discussions on self-mutilation and suicide and the analysis of suicide among the gifted are most interesting.

The content of this book is too extensive to summarize, and the danger of generalization when it is not justified is great. Those intrigued by the drama of suicide will find a journey through this topography of self-destruction worthwhile. The reader should be cautioned that it is not a light or pleasant journey and that he or she might well complete this laborious trip with the feeling of not being sure where he or she was or where he or she is going.

Piscataway, N.J.

The Art of Adoption: The "Hows" and "Whys" by an Adoption Worker Responsible for Over 900 Adoptions, *by Linda Cannon Burgess. Washington, D.C., Acropolis Books, 1976, 154 pp., $8.95.*

This book makes a significant contribution toward understanding the whole process of adoption. The author is knowledgeable in her field and writes of her experiences clearly and well, holding the reader's interest throughout.

She begins with a chapter on "The Social Worker and the Agency," stressing the prime responsibility of the agency in deciding what will happen to the unwanted child. She writes of adoptive parents and what their emotional problems might be. Her orientation is Freudian, but not markedly so. The chapters on biological mothers and fathers tell of the often poignant struggle in relinquishing a child for adoption. Her chapter on involved grandparents, adoptive or natural, is particularly interesting and rather surprising in that it reveals the amount of influence these relatives often bring to bear in cases of adoption.

Other chapters deal with the child, the questions that will inevitably be asked, and the outside influences that will affect the child's attitudes. Burgess discusses the problems of suspected rejection, genetic heritage, and court decisions. Opening Pandora's box, she brings up the issue of the adopted person seeking his or her natural parents. This is a current and rather controversial issue, and some adopted individuals are demanding that agency and court records be made available to them. The author leans toward the idea of giving the child early knowledge of the natural parents if feasible, but she points out that a great deal depends on the emotional maturity of the adoptive parents—some can tolerate it and some cannot.

This book is written primarily for adopted children and their parents, both natural and adoptive, but it would make good reading for psychiatrists, psychologists, and social workers. The generally accepted concept is that the child should be told of his or her adoption as early as possible, but the fact of his or her natural parents remains, only to rise later in life.

The author is pragmatic, aware of the many problems that can occur in adoption and how society views them. She writes without prejudice and presents an interesting and often moving account of her experiences over the years in this rather difficult field.

STUART M. FINCH, M.D.
Tucson, Ariz.

Bringing Up Children Overseas: A Guide for Families, *by Sidney Werkman, M.D. New York, N.Y., Basic Books, 1977, 215 pp., $9.95.*

This slim volume, written primarily for families who are about to move to a foreign country, is also a useful guide for professionals whose advice is so often sought. It is written in simple, commonsense, practical language, e.g., under the chapter title "The Lure of Living Overseas" are such headings as "romance and adventure," "a wish to discover a heritage," "escape," "the hope for eternal renewal," "the Maharaja syndrome," "the Nipa Hut syndrome," "the gold at the end of the rainbow syndrome," and "the 'eternal wanderer' syndrome."

Bringing Up Children Overseas is a guidebook that is developmentally oriented in its discussion of the conflicts children and youth have over moving and travel. The author emphasizes the family's need to anticipate disappointments and to reorder priorities and set goals in the new setting. He describes the very different and delicately complicated nature of relationships with foreigners, pointing out that the need to change expectations and behavior in adapting to a new culture is not theirs but ours.

Much of the book is reminiscent of the Peace Corps' discovery of and experience with culture shock. The author discusses the effects of a different culture on identity formation in depth, providing a particularly good and sensitive discussion of the old world of servants who are traditionally and customarily used as caretakers for children in other countries. He covers not only the problems associated with the involvement of these caretakers but also their eventual loss to the child. The chapter on education in other countries is particularly useful, as is the one outlining special problems of adolescents.

Throughout the book Dr. Werkman takes an optimistic point of view, minimizing rather than maximizing problems but exposing them realistically, offering practical tips, and emphasizing self-help. The chapter on specific fears of children and their meaning, including the author's advice as to what to do about them, is nicely paired with a chapter on common minor medical problems.

Those who have lived in another country will find that this book reads like a diary; those who are about to move to another country, whether for civilian or military purposes, will find it a gold mine of invaluable information on what to anticipate and how to cope. It is packed with practical suggestions ranging all the way from having the American youngster carry a pocket tape recorder with tapes of music with him or her to placing a bucket of manure on the porch to free the bedroom of flies during the night. The psychiatrist who is called on for advice will do well to have this book on his or her shelf.

JOHN F. MCDERMOTT, JR., M.D.
Honolulu, Hawaii

The Delinquent Way of Life: Third Report of the Cambridge Study in Delinquent Development, *by D.J. West and D.P. Farrington with the assistance of Gwen Gundry, B.J. Knight, and S.G. Osborn. London, England, Heinemann, 1977, 203 pp., £6.00.*

This third report of the Cambridge Study in Delinquent Development is a remarkable follow-up study of some 400 young men born in 1951–1954. The research subjects were chosen in 1961–1962 because they were attending six adjacent primary schools in a working-class area of London. This report is based primarily on interviews with 389 of the subjects in 1971–1973, plus a review of their official records of delinquency. One hundred one of the subjects had an official conviction for one or more offenses committed before the date of the interview.

Contrary to the authors' expectations, they found that convicted delinquent subjects were not typical representatives of the whole group. The delinquent subjects showed behavior traits strongly supporting the concept of a delinquent character. The subjects were more immoderate in their smoking, drinking, gambling, and sexual habits. They drove more recklessly and were more often spendthrift. They were not interested in reading or in further education. Their job records were less stable than those of the nondelinquent subjects. The delinquent subjects earned more money per week, but they were typically in jobs without prospects for advancement.

The authors found that many of the hard-core recidivist delinquents who were antisocial at age 18 had already been recognized as deviant when they were as young as age 8. It seems that delinquent character formation begins early. An inherited temperamental disposition might be a contributing factor, but lack of attention, affection, and consistent training from parents during the formative years is a more obvious and probably more important factor. In later years, according to the authors, "the acquisition of antisocial habits from already delinquent companions, and the stigmatizing effects of being identified with the problem group of truants, rebels, and convicted persons probably reinforce deviant life styles."

This is a monumental study with surprisingly complete follow-up. Statistical analysis is extensive and resourceful. It deals with extent of delinquency and catalogues a large number of predictors both in family background and in the early development of delinquents.

The authors are cautious about their suggestions for action. They suggest that it might be desirable to concentrate some of the scarce social resources to help the most needy, the educationally retarded offspring of large, poor, problem families. They suggest that a sample of vulnerable young males could be randomly allocated to several groups, one of which would be a control group left to the usual resources of existing welfare agencies and each of the others offered a different kind or combination of special help. Follow-up over a period of time should indicate the advantages of each method.

The authors consider delinquency in its quantitative aspects. They make no effort to differentiate qualitatively different subgroups of delinquents. They group only by extent of delinquency and/or recidivism.

RICHARD L. JENKINS, M.D.
Iowa City, Iowa

Psychosomatic Medicine: Current Trends and Clinical Applications, *edited by Z.J. Lipowski, M.D., Don R. Lipsitt, M.D., and Peter C. Whybrow, M.D. New York, N.Y., Oxford University Press, 1977, 617 pp., $19.50.*

This volume should have considerable general appeal to *Journal* readers. It consists of a collection of papers originally published in 1975 and 1976 by the *International Journal of Psychiatry in Medicine*. The papers as a group are comprehensive, current, and well organized. If the reader's goal is to read an up-to-date and sophisticated overview of the current trends and clinical applications of psychosomatic medicine, this text provides an elegant experience.

The contents consist of 50 papers, including a timely introduction and epilogue, organized into five parts, each dealing with a salient aspect of psychosomatic medicine. Part one provides perspective with 10 largely theoretical and historical papers under the heading Current Trends in Psychosomatic Theory: The Mind-Body Complex and the External Environment. Part two is titled Intermediate Mechanisms: From Psychological Response to Physiological Reaction. Three brilliant review papers are included here that address neurophysiological, neuroendocrine, and immune mechanisms. An entire volume could easily be given over to papers on mediating mechanisms; however, the editors restrict this rapidly evolving literature to the three major and relevant systems.

Part three, Current Trends and Methodological Approaches in Psychosomatic Research, is concerned with quantification and research methodology. This section is subdivided so that clinical, epidemiological, psychophysiological, and animal studies are presented separately. One quickly appreciates the magnitude of the existing research in psychosomatic medicine in spite of the many quantification obstacles.

Psychosomatic Approach in the Practice of Medicine, part four of the book, provides a modernized look at therapeutic and management issues. Advances in psychopharmacology, biofeedback, behavior modification, and diagnostic principles are pragmatically addressed. The importance of the doctor-patient relationship is appropriately emphasized as a salient contribution of psychosomatic medicine in the 1970s.

Lastly, part five deals with the most unripened aspect of

psychosomatic medicine, namely, teaching. Student and institutional resistance are generally acknowledged. Although the authors identify historical and methodological problems, the reader might be left with a feeling that the resolution of problems in the teaching of psychosomatic medicine is not on the near horizon.

It is difficult to find fault with such a comprehensive and scholarly volume. Admittedly, psychosomatic medicine is many things to many people; however, the clinician has long tended to consider psychosomatic medicine exclusively in terms of the patient who presents with somatic symptoms in the context of psychosocial stress. Patients with psychosocial manifestations of somatic pathophysiology probably deserve more attention. Those suffering from the psychosocial sequelae of dementia, complex-partial seizures, or pharmacologically induced behavior disorders are examples of this very large and often neglected group.

This book is reasonably priced and reflects the work of outstanding contributors in the field. Its organization and clinical relevance allow for easy reading, and its content provides an excellent reference source. It is a pleasure to recommend it to all *Journal* readers.

WILLIAM E. THORNTON, M.D.
Charleston, S.C.

Heroin Addiction: Theory, Research, and Treatment, *by Jerome J. Platt and Christina Labate. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1976, 398 pp., $19.95.*

This book was written, according to the authors, for two purposes. One was to provide a survey of knowledge about the subject of heroin addiction. The second was to provide a wider perspective than could be obtained from the selective sampling of the literature that characterizes most of us in our professional reading habits. To accomplish their purposes the authors reviewed more than 2,000 published references. Of these, 512 were selected for material presented in the book, and another 494 citations published since 1970 were selected as a supplementary reference list. Thus the book provides a useful selected bibliography on the subject of heroin addiction.

There are four main parts to the book, all of which contain useful reviews of the varied and frequently conflicting findings reported in the literature. Value judgments on the part of the authors are rare, and the useful perspective they provide is that there are no simple answers to this complex and puzzling problem.

Part one deals with the historicolegal context of heroin addiction on international, national, and state levels. The authors provide concise accounts of some of the important legal decisions and legislative acts that have brought us to the place where addiction is no longer a crime and medical treatment is recognized as having a useful role in dealing with the problem.

Physiology and pharmacology comprise part two. Dr. Platt, a psychologist, and Ms. Labate, a research associate, have done an impressive job of lucidly describing important findings and areas of controversy. Experts in pharmacology may argue with their content and organization, but for most psychiatrists these chapters provide a useful review and update. I learned, for example, that monoacetyl morphine, an intermediary metabolite of heroin, penetrates the blood-brain barrier and is absorbed more rapidly by cerebral tissue than morphine itself. I had always viewed as street folklore the statements of many addicts that heroin produces a faster high than morphine. Now research findings have confirmed that aspect of our patients' experiences.

Part three, Explaining Heroin Addiction, is the heart of this book. The authors, who have contributed to research exploding the myth of the addictive personality, carefully review the theories of addiction, psychopathology, and the psychosocial aspects of heroin addiction. Much of the material in this section of the book applies equally well to all chemical dependence, including alcoholism. Any physician working with drug-abusing patients will find the scope of his or her understanding increased by the material the authors present here.

The last section of the book, describing treatment approaches, was for me the most frustrating. The authors are very fair in their descriptions and provide particularly good coverage of the use of methadone in treating heroin addiction. However, they provide little synthesis or interpretation of the findings. In their description of psychotherapy as a treatment modality, they state, "The literature on psychotherapy with heroin addicts is both sparse and unencouraging." They end on this negative note rather than suggesting that psychotherapy will probably work only in the context of a structured treatment program which can also deal with the addict's behavior outside psychotherapeutic sessions. Vaillant cogently made this case in 1975 (1); this article is not cited by the authors.

My frustration is, of course, unfair. Specialists in history, pharmacology, or personality theory would be similarly frustrated with the other three sections of the book, which I found loaded with useful information. The authors have succeeded well in achieving their objectives. They have also produced a book that will serve as a useful stimulant and resource for any physician wrestling with the complex task of treating addiction.

Schizophrenia: Biological and Psychological Perspectives, *edited by Gene Usdin, M.D. New York, N.Y., Brunner/Mazel, 1975, 144 pp., $8.95.*

The professional lives of most of those who read this review will be mainly devoted to the important matter of patient care. Few are likely to have much personal acquaintance with the investigations going forward in brain chemistry, the epidemiology of the schizophrenias, and psychopharmacology. Fewer still will read systematically the very specialized journals in which much of the original research is published. The American College of Psychiatrists, devoted to promoting postgraduate education in our profession, recognizes these facts and offers in this short, informative book four excellent review articles and three perspective-giving papers. The reviews are compact and reward a little study.

Dr. Arvid Carlsson's piece on the pharmacology of schizophrenia is a clear, uncluttered exposition of the interaction of antipsychotic agents, the neurotransmitters in brain synapses, and the importance of the major dopaminergic pathways. A clinician who wants to know how his or her pre-

scriptions work will find the main facts and theories spelled out here in 19 pages. Mandell's chapter expands on the current state of neurobiochemistry. He discusses the neurotransmitters, their discharge from presynaptic membranes, their uptake, and the inhibition of their action at postsynaptic receptor sites. He also reviews the factors that govern receptor function over longer periods, substrate uptake mechanisms, and delayed alterations in enzyme activities and amounts.

Chodoff and Carpenter discuss the psychogenic theories of schizophrenia, acknowledging the many problems of diagnosis and method that beset such research. The psychoanalytic hypotheses include those of conflict, thought disorder as a defense against intolerable affect, and schizophrenia as the consequence of a defect in structure resulting from defective internalization of objects and leading toward a fragile sense of self.

Chodoff and Carpenter mention the studies of Lidz, Wynne, and others dealing with disturbed families and their communication patterns as well as the destructive influences of parental egocentricity and narcissism. They suggest that the last several decades of psychogenetic inquiry have resulted in a consensus: schizophrenia most characteristically emerges in people who come from a disturbed family environment with faulty, idiosyncratic communicative processes, who are handicapped by poor early object relationships, and who are subject to an agonizing ambivalence in attitude toward interpersonal closeness.

Robert Cancro discusses the impact of genetic studies on the understanding of etiology and prevention. He sets out the main outlines of contemporary genetic evidence from studies of consanguinity, twins, and adoption clearly and without intruding too much detail. He also discusses the implications of genetic understanding for eugenic programs and prophylaxis.

A genetic factor in the prevalence of schizophrenia has now been demonstrated beyond reasonable doubt, but the exact nature of the factor is yet to be defined. Cancro speculates that more than one gene is involved and that more than one genetic constellation can set the stage for a schizophrenic breakdown when the patient falls into the correct evoking environment. Just what the characteristics of that environment might be, of course, we do not know, but Cancro mentions a range of psychological, social, family, and dietary possibilities. His chapter is a particularly fine one in that it demonstrates clearly how neither hereditary-chemical factors nor environmental-psychological ones alone are sufficient to explain the prevalence of the schizophrenias. The view that both genetics and environment contribute to the genesis of these psychoses is shared by other writers in this collection.

Klerman defends the medical or disease model of schizophrenia, pointing out parallels to such disorders as arthritis and hypertension. Although we have seen real advances in the institutional management of the schizophrenias in recent years, much remains to be done in the development of adequate aftercare. Although prolonged hospitalization is known to be harmful, there are insufficient rehabilitative, vocational, and residential resources available for adequate support of many discharged patients.

Fewer and fewer studies are now published on the utility of family, group, or individual psychotherapy; the lack of new evidence might partially account for the fact that no chapter devoted to psychotherapy alone appears in this book. In spite of the fact that many clinicians are convinced that psychotherapy is lifesaving in some cases and that it is useful in reducing morbidity, there are few studies that definitely prove this. The lack of a chapter on psychotherapy is regrettable, but most recent advances in schizophrenia studies are in the chemical-hereditary area. Many of the authors of the perspectives in this book agree that social therapies geared to the problems of the here and now are important in the manangement of the recovering patient, as is the prescription of appropriate antipsychotic drugs.

The book is rounded out with chapters by Roy Grinker, Sr., and Morris Lipton. Grinker comments on the evolution of schizophrenic research over the past 50 years, and Lipton discusses the impact of biological studies on theory and treatment.

The various articles are accompanied by useful bibliographies. *Schizophrenia: Biological and Psychological Perspectives* is an excellent general review for clinical psychiatrists who wish to keep informed as well as for residents and other physicians.

JOHN T. MALTSBERGER, M.D.
Boston, Mass.

The Experience of Dying, *edited by E. Mansell Pattison. Englewood Cliffs, N.J., Prentice-Hall, 1977, 335 pp., $10.95; $4.95 (paper).*

Some might say that the Age of Death emerged with the publication of Feifel's *The Meaning of Death* in 1959 (1). Since then, the field of thanatology has undergone a development all its own. The myths and taboos, the silence and neglect, and the fears and guilts that once enshrouded the topics of death and dying no longer encumber the enlightened clinician. Perhaps we have reached the stage, not dissimilar to Erik Erikson's idea of industry versus inferiority (2), in which the practitioner is receptive to instruction.

This book is of the type Cohen categorized as having a developmental-psychopathological perspective (3). Dr. Pattison's stated goal is "to provide a broader, in-depth portrayal of the dying process in its many personal forms." To accomplish that goal, he complements his erudition and his 10 years of clinical experience in dealing with dying patients with the thanatological expertise of 24 knowledgeable contributors. The 29 chapters of this book are addressed to those who must manage and care for the dying person. The topical bibliography provides the student with recent references to relevant issues in thanatology.

The first part of the book presents a theoretical background to understanding the dying process. Of particular interest is chapter 4, "The Experience of Dying," in which Dr. Pattison introduces the concept of the living-dying interval. Because each of us has certain life-span expectations according to which we plan and arrange our lives, we may be ill-prepared to encounter a shortening of those expectations. The reality of illness or accident may confront us with the crisis of knowledge of our own death. The detached and nebulous idea that all things eventually die becomes the personal and unavoidable idea, "I am dying now." The period between the crisis of knowledge and the point of death is the living-dying interval, more prevalent today because of major advances in medical therapeutics. Dr. Pattison divides this interval into three clinical phases: the acute crisis, the chronic living-dying, and the terminal phase. Within these three phases the practicing clinician can intervene and help the dying patient.

Parts two through seven of the book underscore the im-

portance of viewing the dying process throughout the life's cycle. Too little systematic scientific work has dealt with the cognitive meaning of death and the typical coping styles of the dying. Dr. Pattison's skill in selecting contributors able to elucidate the dying process, with its different reflections of the influence of such illness contexts as accidents, infections, malformations, organ transplants, and cancers, is both innovative and enlightening.

In part eight of this book, Styles of Dying, Dr. Pattison debunks the formalized stages of dying (4), expands on the notion of ego coping mechanisms in dealing with the stress of the living-dying interval, and, most importantly, gives the reader some guidelines for helping dying patients. In sum, that helping involves befriending the patient, providing "the corrective, supportive, inquisitive, challenging, accepting give and take that comprises our valued relationships with others."

In conclusion, aside from some irritating oversights by the copy editor—for example, Drs. E. Shneidman, A. Weisman, and E. Lindemann's names were misspelled—this book is both clinically informative and sensitively written. Dr. Pattison has done a useful service for all those who deal with the dying patient and his or her family.

Stockton, Calif.

The Basic Neurology of Speech, 2nd ed., *by Michael L.E. Espir, M.A., M.B., and F. Clifford Rose, M.B., D.C.H. Oxford, England, Blackwell Scientific Publications (Philadelphia, Pa., J.B. Lippincott Co., distributor), 1976, 143 pp., $12.00 (paper).*

This book is written primarily for speech therapists, but it provides concise and enlightening information for the psychiatrist interested in communication and its neurological aspects. One of the very attractive features of this book is its brevity. In less than 150 pages the authors succinctly present a difficult subject in a readily understandable fashion. The information they provide is not new, but it is usually scattered throughout larger textbooks.

The first part of the book describes the various types of speech and language disorders (stammering, dysarthria, and dysphonia) and their neuroanatomical and neurophysiological substrates. The second part gives a concise account of brain disorders that can influence speech and language, including a particularly good summary of the speech disturbances in epilepsy and dementia.

In conclusion, this is a valuable book for the psychiatrist who might tend to forget the many intermediate steps between thought and expression.

PHILIPPE E. CHANEL, M.D.
Washington, D.C.

The Alcoholisms: Detection, Assessment, and Diagnosis, *by George R. Jacobson, Ph.D. New York, N.Y., Human Sciences Press, 1976, 414 pp., $19.95.*

The author's purpose in this book is to select from the psychological tests used in studying alcoholism those which might be useful in identifying the prealcoholic person or the individual at risk, in assisting in taking preventive measures, and in detecting the alcoholic person at the earliest possible point in the development of the disorder. On this basis he reviews 12 tests that have been applied for these different purposes.

The following tests were chosen: the Alcadd Test (1949), the Manson Evaluation (1949), the Essential Readdictive Alcoholism Dimension (1961), the Iowa Alcoholism Intake Schedule (1965), the MacAndrew Alcoholism Scale (1965), the Alcoholism Assessment Interview (1965), the Alcohol Use Questionnaire (1969), the Bell Alcoholism Scale of Adjustment (1969), the Michigan Alcoholism Screening Test (1971), the Mortimer-Filkens Test (1971), the Criteria for the Diagnosis of Alcoholism (1972), and, finally, the Alcohol History Form—Alcoholism Severity Scale (1973).

The author describes each of these psychometric measures in detail in individual chapters, using a format that indicates the source of the most significant documents relating to the development of the test, its availability, a description and details of the test, the technique of its administration, and comments on the test as well as the training and experience necessary to properly administer, score, and interpret it. He includes a section on the development of each test and its reliability and validity. He expresses his own subjective evaluation of each test and its possible relationship to treatment planning and predicting outcome. He also makes suggestions as to which test might be particularly useful with special populations, such as drinking drivers, women, young people, poverty groups, and others. He discusses the advantages and disadvantages of each test and concludes with a helpful summary of each.

The author's scholarly and critical examination of these tests provides an overview of their formulation and applicability. The printing and format of the monograph make for ready accessibility. If there is any serious criticism of the presentation, it would be of its terseness. For those interested or involved in the study of the prevention and management of alcoholism, the survey provides a useful guide in assessing and selecting psychometric measures that might be most appropriate for a particular task. The book can be recommended as a useful addition to one's working library.

ALBERT A. KURLAND, M.D.
Baltimore, Md.

Treatment and Rehabilitation of the Chronic Alcoholic. The Biology of Alcoholism, Vol. 5, *edited by Benjamin Kissin and Henri Begleiter. New York, N.Y., Plenum Press, 1977, 614 pp., $39.50.*

This fifth and final volume of a comprehensive review of the biological, psychological, and social aspects of alcoholism is devoted to the treatment of the alcoholic patient. It is one of the best books that I have read on this subject—is eminently readable and interesting in spite of the large amount of material presented. The many current treatment methods are well described and evaluated, and the historical background of treatment and extensive resource references

relating to this subject are provided. The wide range of information contained in this book is accurate, thorough, and up-to-date.

As the authors point out, the various remedies proposed for alcoholism often have strongly biased cohorts either for or against them. This suggests the complexity of this medical-social problem and the difficulty of obtaining independent appraisal of the relative effectiveness of different treatment modalities. There are many kinds of alcoholic patients; the therapist must individualize treatment to fit the needs of each patient. Usually a multipronged approach to the problem is required, as outlined in this book. Alcoholic patients constitute a markedly heterogeneous population with widely disparate needs; what helps one victim might not be indicated for another.

A broad spectrum of treatment modalities is available. Among those discussed in this book are medical; pharmacological (including disulfiram [Antabuse], lithium, antidepressants, and tranquilizers); psychotherapy; counseling; behavior modification (including aversive and operant conditioning and motivation); social, cultural, and religious therapy; family and group therapy; therapeutic communities; halfway houses; orientation lectures; and, of course, Alcoholics Anonymous. The authors stress the absolute need for therapists to be nonjudgmental, nonpunitive, and objective. They also stress the need for continuity of care.

The book quotes Keller's law: "The investigation of any trait in alcoholics will show that they have more or less of it." Keller concluded that "alcoholics are different in so many ways that it makes no difference." The special validity of this book is that all of the many treatments are as thoroughly evaluated as is possible with the current level of our knowledge. This enables the therapist to prescribe objectively and intelligently the treatment or treatments best suited to help his or her patient.

FREDERICK LEMERE, M.D.
Seattle, Wash.

Consciousness and Self-Regulation: Advances in Research, Vol. 1, *edited by Gary E. Schwartz and David Shapiro. New York, N.Y., Plenum Press, 1976, 385 pp., $18.95.*

Cognitive therapies—those focused on conscious thought content and the here and now—have elicited widespread interest. Persuasion, long considered a historical relic, has attained legitimacy through Jerome Frank and celebrity through Albert Ellis and Aaron T. Beck. "Rational thinking," self-taught or tutored, and ideation-oriented behavior therapy techniques are respectable in scientific circles. Indeed, psychology, we are told, has already "gone cognitive," and cognition has been hailed as the Cinderella of psychiatry.

The basic sciences underlying cognitive therapy would probably include the venerable psychological disciplines of introspectionism and associationism. To these would be added the areas encompassed by *Consciousness and Self-Regulation.*

As a result of their successful interdisciplinary seminars at Harvard, Gary Schwartz and David Shapiro were commissioned to edit a series of volumes devoted to the psychophysiology of consciousness, emotion, and self-regulation. The entire series is appropriately dedicated to William James, reverence for whom in this first publication does not preclude disagreement.

This first volume's nine chapters are mainly review articles by pioneers in their respective fields. Ernest R. Hilgard, on the basis of his classic hypnosis research, applies to pain perception his developing theory of multiple simultaneous streams of awareness. Karl H. Pribram recounts his 40 years' work in tracking the limbic system. Electroencephalographers trace out memory storage and retrieval, try to delineate hypnotic trance and altered states of consciousness, and monitor dreaming in search of psychological and physiological meanings.

Data and insights of direct relevance to psychiatric practice are concentrated in the two chapters devoted to clinical research. Reading Thomas D. Borkovec, one makes a startling discovery about anxiety, the key concept in the psychodynamic understanding of neurosis and other emotional disorders: patients, therapists, and researchers have been making the same error in believing that all anxiety is alike. Although all the answers are by no means at hand, at least some long-neglected questions are now being asked.

Borkovec subclassifies the experience of anxiety into physiological, subjective, and behavioral components. These components can then be further broken down, e.g., distinctive physiological profiles can be identified by means of Mandler's Autonomic Perception Questionnaire. Phobias themselves may have unique patterns: in snake phobias, characterized by determined avoidance of exposure to snakes, autonomic disruption is minor; in public speaking anxiety, by contrast, there is major autonomic disruption.

Therapeutic interventions can be shown to be specific in their effects. The mobilization of hope is a potent healing force only when autonomic factors are insignificant. When physiological arousal is the key sustainer of neurotic fear and behavior, cognitive interventions are relatively ineffective; in this instance such treatments as desensitization, flooding, and biofeedback are required. Drugs that alter the limbic system or autonomic nervous system might be indicated.

Why do some individuals capitulate to a level of autonomic arousal that is resisted easily by others? Borkovec should probably consider such differences in the capacity to endure unpleasant affects. A concept of ego strength would accord with Meichenbaum's principle, stated in the book's other clinical research chapter, that men are not moved by what they feel but by what they say to themselves about what they feel. This principle is a restatement of what might be called the cognitive creed: Epictetus' observation that "men are not moved by things but by the views which they take of them."

In his treatise on how to talk to oneself constructively, Donald Meichenbaum describes what he claims to be the final common pathway of successful psychotherapy—the patient's altering his or her internal monologue in order to facilitate adaptive behavior. Meichenbaum advocates the teaching of a generalized problem-solving approach that the patient can apply throughout his or her lifetime. An anxious individual with sweaty palms and tachycardia learns to reinterpret these phenomena as signals to employ coping techniques in which he has been trained (e.g., relaxation).

Each of the seven basic science chapters presents a new technical nomenclature and research methodology. For the psychiatric clinician this is rugged foreign terrain. On the whole, to traverse it requires more exertion than it is worth. Without considerable further study the reader will not learn enough about any field to be able to devise his or her own practical applications or hypotheses. He or she will have to be content with the smaller joy of sifting out choice bits of fact and conjecture that might be useful.

My personal selection of useful bits of information include the following:

There are many functional differences between the more concrete and verbal left cerebral hemisphere and the more dreamy, abstract right.

The basal ganglia control not only motor function but sensory input.

Seemingly irreversible deficits in brain function might one day be recouped. Information appears to be stored diffusely throughout the brain. Following destruction of a primary storage center, information could theoretically be recalled from secondary centers that were previously silent due to a signal-to-noise ratio lower than that for the primary center.

Sensory-deprived subjects are more amenable to attitude change than control subjects.

REM deprivation has not proved to be disruptive for the dreamer. Nor is it unquestioned that REM sleep restores the mind while NREM sleep restores the body.

Hypnotic susceptibility can be augmented by instructing subjects in how to experience hypnosis and by correcting anxiety-inducing misconceptions about hypnosis.

It can be predicted that Schwartz and Shapiro's later volumes will contain fewer speculations and more conclusions. Meanwhile, however, the first volume of *Consciousness and Self-Regulation* is not the place to start learning about cognition. For psychiatrists, less strain and more immediate profit will attend the examination of Beck's familiar if limited perspective (1) and Michael J. Mahoney's shrewdly critiqued compendium (2).

The Impact of Biology on Modern Psychiatry, *edited by Elliot S. Gershon, M.D., Robert H. Belmaker, M.D., Seymour S. Kety, M.D., and Milton Rosenbaum, M.D. New York, N.Y., Plenum Press, 1977, 270 pp., $25.00.*

This book comes from a scientific symposium held in Jerusalem in December 1975 to honor the 80th anniversary of the Jerusalem Mental Health Center Ezrath Nashim. The proceedings have the usual mixture of internationally known scientists reviewing work from their laboratories and includes generally less well known scientists presenting findings from specific projects. The uniqueness and value of this publication comes primarily from the latter, since the work of a number of the contributors is readily available in other publications. The proceedings are especially useful in calling attention to important work emerging from several institutions in Israel. This symposium is a collection of individual reports with little attempt toward thematic organization; therefore, I will briefly describe the contents rather than discuss them.

The book is divided into three sections. The first is titled Neurochemical Studies in Human Psychopathology. Dr. Herman M. van Praag provides an excellent overview of the work of his laboratory relevant to cerebral dopamine metabolism in relationship to pathogenesis and treatment of psychotic disorders. Dr. Goran Sedvall reviews the work conducted in the Karolinska Institutet examining CNS biochemical mechanisms relevant to antipsychotic drug action in humans. Dr. Samuel Gershon reviews the relationship of psychopharmacological agents to psychiatric diagnosis. The remainder of this section is composed of reports from several workers in Jerusalem. Drs. Ebstein and Belmaker compare lithium and haloperidol action on human peripheral β-adrenergic adenylate cyclase. Dr. Elizur and colleagues examine lithium and electrolyte distribution in relationship to neurotoxic lithium effects, and Dr. Samuel reports on a new method using oxygen-18 to measure monoamine turnover. There are also reports on levels of antibodies to viruses in various psychiatric illnesses by Drs. Rimon and Halonen and a report on a tissue-binding factor in the serum of schizophrenic patients by Dr. Witz and coworkers.

The second section is titled Catecholamines and Behavior. The six papers here are all interesting, but they do not constitute a coherent conceptual arrangement. They range from Dr. Youdim's discussion of factors influencing CNS biogenic monamine activity to Dr. Korczyn's reports on "Combined Use of Neuroleptic Drugs." Arnold Mandell provides a delightful piece critiquing the old and suggesting a new biochemical theory for psychiatry.

The final section, Genetic Studies in Psychiatry, presents an overview of current genetic strategies relevant to the major psychoses. This section has thematic organization, which makes for easy reading and utility as resource material. The genetics of schizophrenia is discussed by Seymour Kety, affective illness by Elliott Gershon, schizo-affective illness by Julien Mendlewicz, and diagnostic issues in twin studies by Margit Fischer. Drs. Belmaker and Ebstein relate genetically influenced enzymatic activity to the biogenic amine hypotheses of psychiatric disorders.

The Impact of Biology on Modern Psychiatry is disappointing in its contrast between title and content. The title suggests that the reader will receive a historical review of developments in neurobiology and genetics, their influence on psychiatric research, and the eventual impact on psychiatry in general. However, the reader will find a conventional symposium dealing with biological issues in psychiatry without any perspective on the growth of biological psychiatry, the relationship of neurobiology to the development of psychiatry, or consideration of implications for the future. One can merely note that the symposium itself is an example of the increasing influence of biology on modern psychiatry.

WILLIAM T. CARPENTER, JR., M.D.

Brain Metabolism and Cerebral Disorders, 2nd ed., *edited by Harold E. Himwich. Holliswood, N.Y., Spectrum Publications (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1976, 361 pp., $28.00.*

For those of us who knew Harold Himwich, this edition conjures up fond memories of a most imaginative and creative human being. He was the prototype of the truly multidisciplined scientist whose insights into events in the laboratory and the needs in the clinic bridged this gap and pointed the way for the young to follow.

In contrast to the first edition of this important book, in which all of the chapters were from the same pen, half of the chapters in this edition were written by Dr. Himwich. Nevertheless, these are the chapters central to the theme that

"ontogeny recapitulates phylogeny" first expressed by the late great neuroscientist Hughlings Jackson. It is not in the anatomical but in the functional sense that the theme is threaded through these pages. Himwich championed no single discipline; rather, he emphasized that a knowledge of the developing nervous system called on diverse disciplines to achieve full comprehension. That goal has yet to be achieved, but progress in no modest measure is attributable to Himwich's keen insights and heuristic writings and is exemplified in this second edition of *Brain Metabolism and Cerebral Disorders*.

Unlike many texts written in the popular trend that contain an assortment of papers presented in symposium form at some exotic place, for this book the editor wisely chose contributors whose philosophy of science is consistent with his own and whose expertise contributes significantly.

The three chapters on cerebral metabolism written by the editor serve as a reminder to the young investigator of the many important observations on the brain made at a time when less sophisticated methodology and little knowledge of brain metabolism was available. Many animal data are included in these chapters, which are complemented by a chapter on human brain metabolism by W. Sachs. Dr. Sachs pioneered tracer methods for assessing the relative participation of alternative metabolic pathways in the brains of normal and chronically ill patients. The studies on carbohydrate metabolism are especially informative.

Recognizing that metabolism is intimately associated with brain blood flow, Himwich includes four chapters devoted to a discussion of the anatomical and dynamic aspects of this subject in health and disease. To help in understanding the anatomy of the circulatory tree, neurochemists especially should appreciate the chapter by Professor A.G. Baptista, who presents those morphological characteristics which are distinctive in the human. He blends this with a background concerning the circulation and distribution of blood to the brain. With this background, the chapter on "Regulation of Cerebral Blood Flow" by D.H. Ingvar and N.A. Lassen is very readable and should prove valuable to those less familiar with the fundamental finding that cerebral blood flow (CBF) is ultimately controlled by oxidative metabolism of the nervous system. An area not covered in this chapter concerns the use of short-lived (about 10 minutes) positron-emitting isotopes. Like gamma-emitters, their activity can be detected with the same crystal multidetectors, but such isotopes can be incorporated into metabolically active substrates and provide information not available with current isotope techniques. In spite of this limitation, the chapter provides a meaningful basis for greater in-depth inquiry into a vast array of original papers on the subject.

The chapter by Oldendorf on the blood-brain barrier and on cerebral flow and metabolism in epilepsy, anoxia, ischemia, and edema is most important to the neurologist and neurosurgeon. With the background provided by the chapters by Baptista and Ingvar and Lassen, even the uninitiated is able to gain considerable insights into these most formidable problems.

It is perhaps most appropriate that the book concludes with chapters by Dr. Himwich on the somatic and autonomic divisions of the CNS. From his many years of inquiry into insulin as a means of treatment for mental disorders, he provides us with a tool to delineate the phyletic organization and function of the CNS. It is entirely appropriate as well to conclude this book with a description by Professor Barbeau of the rational approach to parkinsonism, a degenerative disease that appears generally after middle life. Professor Barbeau provides a synthesis of modern neurochemical concepts with a neurophysiological understanding of the underlying deficits. For this he draws on a large population of patients he has personally treated. Despite the progress made since the introduction of L-dopa, the author puts the problem in perspective when he states that this is a generalized disease of pigmented neuron degeneration not restricted to the nigrostriatal pathway.

There is still considerable knowledge to be gained about the developing and aging brain. This book provides a most provocative status report of neuroscience at the time the author took leave of his many friends, colleagues, and students with whom he unselfishly shared his enthusiasms and zest for this subject.

JOHN J. O'NEILL, M.D.
Philadelphia, Pa.

Human Ecology and Cognitive Style: Comparative Studies in Cultural and Psychological Adaptation, *by John W. Berry. New York, N.Y., Sage Publications (Halsted Press, John Wiley & Sons, distributor), 1976, 242 pp., no price listed.*

The author is an associate professor in the Department of Psychology, Queen's University, Kingston, Ont., Canada, and is also an associate editor of the *Journal of Cross-Cultural Psychology*. This book is one of a series titled Cross-Cultural Research and Methodology and would be considered a fair sample of contributions of its genre. It is a report of a decade's work. The author attempts a semiquantitative description of an extremely large conceptual canvas, reporting data on 21 sample groups from 11 different cultures. From these data he attempts to construct a theoretical model integrating ecological, cultural, and behavioral dimensions of behavior.

Berry uses ethnographic and psychological methods, combining anthropological and psychological approaches. The result is likely to be incomprehensible to psychiatrists without anthropological training. Further, it would interest only those with a narrowly focused research interest. The "cognitive styles" referred to in the title allude to the field-dependent-field-independent dimension of Witkin and associates, roughly subsumed under the theory of psychological differentiation. The principal finding reported is that members of preliterate, nomadic, loose cultural groups tend to be field independent, but members of tight, sedentary, agricultural groups tend to be field dependent in their cognitive styles.

Overall, Berry's presentation suffers from serious faults and limitations that most readers will find, at the least, very confusing. His model appears to be more complex than the data, and his subject matter is too obscure to be of interest to more than a handful of anthropologically oriented researchers in cross-cultural psychology.

This Month's Reviewers

ALLAN BEIGEL, M.D., is Associate Professor of Psychiatry, University of Arizona College of Medicine, Tucson, Ariz.

IRVING PHILIPS, M.D., is Director, Child and Adolescent Psychiatry, Langley Porter Neuropsychiatric Institute, University of California, San Francisco, School of Medicine, San Francisco, Calif.

JOHN C. DUFFY, M.D., is Professor of Psychiatry, Uniformed Services University of the Health Sciences School of Medicine, Bethesda, Md.

HARRY A. WILMER, M.D., Ph.D., is Professor of Psychiatry, University of Texas Health Science Center, San Antonio, Tex.

WILLIAM T. MCKINNEY, JR., M.D., is Professor and Chairman, Department of Psychiatry, University of Wisconsin Medical School, Madison, Wis.

CLAYTON PETTIPIECE, M.D., is Director, Immanuel Medical Center, Omaha, Neb.

DAVID F. BERRY, PH.D., is a Clinical Psychologist in private practice in West Hartford, Conn.

IRWIN N. PERR, M.D., J.D., is Professor of Psychiatry and Professor of Community Medicine, Rutgers Medical School, College of Medicine and Dentistry of New Jersey, Piscataway, N.J.

STUART M. FINCH, M.D., is Lecturer, University of Arizona College of Medicine, Tucson, Ariz.

JOHN F. MCDERMOTT, JR., M.D., is Professor and Chairman, Department of Psychiatry, John A. Burns School of Medicine, University of Hawaii, Honolulu, Hawaii.

RICHARD L. JENKINS, M.D., is Professor of Child Psychiatry, Emeritus, University of Iowa, Iowa City, Iowa.

WILLIAM E. THORNTON, M.D., is Associate Professor of Psychiatry and Associate Professor of Family Practice, Medical University of South Carolina, Charleston, S.C.

JOHN N. CHAPPEL, M.D., is Professor of Psychiatry, School of Medical Sciences, University of Nevada, Reno, Nev.

JOHN T. MALTSBERGER, M.D., is Assistant Clinical Professor of Psychiatry, Harvard Medical School, Boston, Mass.

MICHAEL F. HEIMAN, M.D., is Chief, Medical-Dental Staff, Stockton Residential Facility, Stockton, Calif., and Clinical Instructor, Department of Psychiatry, University of California, Davis, School of Medicine, Davis, Calif.

PHILIPPE E. CHANEL, M.D., is Assistant Professor of Psychiatry, George Washington University School of Medicine, Washington, D.C.

ALBERT A. KURLAND, M.D., is Research Associate, Maryland Psychiatric Research Center, Department of Psychiatry, University of Maryland School of Medicine, Baltimore, Md.

FREDERICK LEMERE, M.D., is Clinical Professor of Psychiatry, University of Washington School of Medicine, Seattle, Wash.

JOSEPH S. SILVERMAN, M.D., is Clinical Assistant Instructor, Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine, Pittsburgh, Pa.; he is also in private practice in Altoona, Pa.

WILLIAM T. CARPENTER, JR., M.D., is Director, Maryland Psychiatric Research Center, Department of Psychiatry, University of Maryland School of Medicine, Baltimore, Md.

JOHN J. O'NEILL, M.D., is Chairman, Department of Pharmacology, Temple University School of Medicine, Philadelphia, Pa.

JAY T. SHURLEY, M.D., is Professor of Psychiatry and Behavioral Sciences, University of Oklahoma, Oklahoma City, Okla.

Books Received

This listing acknowledges the receipt of recent books. Books of particular interest to the readers of this journal will be reviewed as space permits, and copies of the reviews will be sent to the publishers. Books cannot be returned to the publishers.

Primary Prevention of Psychopathology, Vol. I: The Issues, *edited by George W. Albee and Justin M. Joffe. Hanover, N.H., University Press of New England, 1977, 399 pp., $20.00.*

Understanding Psychotherapy: Comparative Perspectives, *by George J. Allen. Champaign, Ill., Research Press Co., 1977, 271 pp., $6.95 (paper).*

Psychopharmacology: From Theory to Practice, *edited by Jack D. Barchas, M.D., Philip A. Berger, M.D., Roland D. Ciarranello, M.D., and Glen R. Elliott, Ph.D. New York, N.Y., Oxford University Press, 1977, 538 pp., $17.95; $10.95 (paper).*

The Implementation Game: What Happens After a Bill Becomes a Law, *by Eugene Bardach. Cambridge, Mass., MIT Press, 1977, 316 pp., $17.95.*

Evaluation of New Drugs in Clinical Psychopharmacology. Drugs Under Experimental and Clinical Research, Vol. 1, No. 1-2, April 1977, *edited by A. Bertelli, G.B. Cassano, P. Castrogiovanni, J. Levine, and J.R. Wittenborn. Barcelona, Spain, J.R. Prous, 1977, 462 pp., $50.00.*

Community Mental Health: A General Introduction, *by Bernard L. Bloom. Brooks/Cole Publishing Co. (Wadsworth Publishing Co.), 1977, 316 pp., $10.95.*

Artificial Intelligence and Natural Man, *by Margaret A. Boden. New York, N.Y., Basic Books, 1977, 537 pp., $17.50.*

Celebrate Yourself: Making Life Work for You, *by Dorothy Corkille Briggs. Garden City, N.Y., Doubleday & Co., 1977, 213 pp., $7.95.*

Behavioral Assessment: New Directions in Clinical Psychology, *edited by John D. Cone and Robert P. Hawkins. New York, N.Y., Brunner/Mazel, 1977, 418 pp., $17.50.*

Anti-Oedipus: Capitalism and Schizophrenia, *by Gilles Deleuze and Félix Guattari; translated by Robert Hurley, Mark Seem, and Helen R. Lane. New York, N.Y., Richard Seaver (Viking Press), 1977, 395 pp., $16.95.*

Surviving in Dentistry: The Sources of Stress, *by J.E. Dunlap, D.D.S. Tulsa, Okla., Dental Economics/PPC Books, 1977, 123 pp., $13.00.*

The Understanding of the Brain, 2nd ed, *by John C. Eccles. New York, N.Y., Blakiston (McGraw-Hill Book Co.), 1977, 244 pp.; $5.95 (paper).*

Current Developments in Psychopharmacology, Vol. 4, *edited by Walter B. Essman and L. Valzelli. New York, N.Y., SP Books (Spectrum Publications), 1977, 264 pp., $25.00.*

New Career Options for Women: A Counselor's Sourcebook, *by Helen S. Farmer, Ph.D., and Thomas E. Backer, Ph.D. New York, N.Y., Human Sciences Press, 1977, 400 pp., $16.95.*

New Career Options: A Woman's Guide, *by Helen S. Farmer, Ph.D., and Thomas E. Backer, Ph.D. New York, N.Y., Human Sciences Press, 1977, 96 pp., $2.95 (paper).*

Biological Bases of Psychiatric Disorders, *edited by Alan Frazer, Ph.D., and Andrew Winokur, M.D., Ph.D. New York, N.Y., SP Books (Spectrum Publications), 1977, 262 pp., $15.00.*

Five Lectures on Psycho-Analysis, *by Sigmund Freud; translated and edited by James Strachey. New York, N.Y., W.W. Norton & Co., 1977, 73 pp., $6.95.*

A Sexual Profile of Men in Power, *by Sam Janus, Ph.D., Barbara Bess, M.D., and Carol Saltus. Englewood Cliffs, N.J., Prentice-Hall, 1977, 187 pp., $9.95.*

Strindberg and Van Gogh: An Attempt at a Pathographic Analysis with Reference to Parallel Cases of Swedenborg and Hölderlin, *by Karl Jaspers; translated by Oskar Grunow and David Woloshin. Tucson, Ariz., University of Arizona Press, 1977, 214 pp., $12.50; $4.95 (paper).*

Primer of Lithium Therapy, *by James W. Jefferson, M.D., and John H. Greist, M.D. Baltimore, Md., Williams & Wilkins Co., 1977, 206 pp., $10.50 (paper).*

Stuttering: The Disorder of Many Theories, *by Gerald Jonas. New York, N.Y., Farrar, Straus and Giroux, 1977, 68 pp., $7.95; $2.95 (paper).*

Medicine and Money: Physicians as Businessmen, *by Joseph LaDou, M.D., and James D. Likens, Ph.D. Cambridge, Mass., Ballinger Publishing Co. (J.B. Lippincott Co.), 1977, 200 pp., $15.00.*

Telegarbage: What You Can Do About Sex and Violence on TV, *by Gregg Lewis. Nashville, Tenn., Thomas Nelson, 1977, 164 pp., $2.95 (paper).*

Alcoholism and Drug Dependence, *edited by J.S. Madden, Robin Walker, and W.H. Kenyon. New York, N.Y., Plenum Press, 1977, 469 pp., $39.50.*

Frontiers of Medicine, *edited by Gordon M. Meade, M.D. New York, N.Y., Plenum Press, 1977, 221 pp., $25.00.*

ANNUAL INDEX

Following is the comprehensive index for volume 134 of the *Journal*, covering all material from January 1977 through December 1977. The complete citation for each article in the author index is listed under the name of the first author; joint authors are listed alphabetically with a cross-reference to the full citation. Book reviews appear in the author index under the name of the reviewer and in the subject index under the heading Books Reviewed; the books are arranged alphabetically by the surname of the book's first author.

Entries other than regular articles, brief communications, and clinical and research reports are indicated as such by the following designations: editorial (editorial); letter to the editor (ltr to ed); in memoriam (in mem); and official actions (off acts).

Author Index

Abel Gene G: book review of Arnold A Lazarus: Multimodal Behavior Therapy. Feb, 221–222
Abraham Abe S: see Daniels Robert S, jt au
Abrams Alan: see Janowsky David S, jt au
Abrams Richard: see Taylor Michael Alan, jt au
Abrams Richard, Taylor Michael A: reply to Augustus F Kinzel: On diagnostic classification (ltr to ed). July, 823
Abrams Richard, Taylor Michael Alan: Catatonia: prediction of response to somatic treatments. Jan, 78–80
Abrams Richard, Taylor Michael Alan: reply to Alan J Gelenberg: Criteria for the diagnosis of catatonia. April, 463
Acharya Semir: see Saran Bru M, jt au
Adams Paul L: book review of AH Chapman: Harry Stack Sullivan: His Life and His Work. Aug, 943–944
Adams Paul L: book review of Dorothea M Ross, Sheila A Ross: Hyperactivity: Research, Theory, and Action. July, 833–834
Adebimpe Victor R: Physical violence in the concept of dangerousness: a case report. Feb, 203–204
Adebimpe Victor R: reply to Lawrence R Doss: On existence of dangerousness (ltr to ed). July, 818

ADDICTIVE PERSONALITY

A note on the addictive personality: addiction to placebos. I Mintz, March, 327

ADMINISTRATION

The function and organization of NIMH (ltr to ed). CL Bowden, Aug, 939–940
Illustrious psychiatric administrators. M Greenblatt, SO Rose, June, 626–630

ADOLESCENCE

Auditory evoked potentials and selective attention in formerly hyperactive adolescent boys. AJ Zambelli, JS Stamm, S Maitinsky, DL Loiselle, July, 742–747
Boarding schools: effects on the mental health of Eskimo adolescents. J Kleinfeld, J Bloom, April, 411–417
Children's rights on entering therapeutic institutions. D Miller, RA Burt, Feb, 153–156
A comparison of outcome in adolescent- and late-onset bipolar manic-depressive illness. GA Carlson, K Jamison, YB Davenport, Aug, 919–922
Contractual agreements with adolescents? (ltr to ed). S Smith, and reply of D Miller, Oct, 1160–1161
Creative "restraints" (ltr to ed). MS Weiner, July, 821
Episodic dyscontrol and family dynamics. HT Harbin, Oct, 1113–1116
The ethics of practice in adolescent psychiatry. D Miller, April, 420–424
Ictal and subictal neurosis (ltr to ed). AD Jonas, and reply of DO Lewis, Sept, 1051–1052
Inhalant abuse in an Indian boarding school. MF Schottstaedt, JW Bjork, Nov, 1290–1293
The multiple family group as a small society: family regulation of interaction with nonmembers. D Reiss, R Costell, Jan, 21–24
Suicide in adolescence. PC Holinger, Dec, 1433–1434

ADOPTION

Not in the best interests of the child (ltr to ed). S Blau, and reply of AD Sorosky, Feb, 210–211
Placement and evaluation of Southeast Asian children (ltr to ed). BL Kennedy, BL Ersley, Aug, 938–939
On unsealing the records in adoption (ltr to ed). JD Goodman, and reply of AD Sorosky, Jan, 95

ADULT BRAIN DYSFUNCTION

Adult brain dysfunction (ltr to ed). DL Hurst, May, 587
More adult brain dysfunction (ltr to ed). WS Rybak, Jan, 96–97

AFFECTIVE DISORDERS

ABO blood groups in unipolar and bipolar manic-depressive patients. RW Shapiro, OJ Rafaelsen, LP Ryder, A Svejgaard, H Sørensen, Feb, 197–200
Anniversary reactions masquerading as manic-depressive illness. JO Cavenar Jr, JL Nash, AA Maltbie, Nov, 1273–1276
Atypical facial pain and hypomania (ltr to ed). JW Jefferson, March, 330
Blood types and affective disorders (ltr to ed). WJ Turner, and reply of RW Shapiro, OJ Rafaelsen, LP Ryder, A Svejgaard, Sept, 1053–1054
Bromocriptine in treating mania (ltr to ed). BM Saran, S Acharya, and reply of RH Gerner, RM Post, WE Bunney Jr, June, 702–703
Committing violent manic patients (ltr to ed). FG Surawicz, June, 704
A comparison of outcome in adolescent- and late-onset bipolar manic-depressive illness. GA Carlson, K Jamison, YB Davenport, Aug, 919–922
A criterion for differential diagnosis (ltr to ed). HD Zucker, March, 330
Cyclothymic disorder: validating criteria for inclusion in the bipolar affective group. HS Akiskal, AH Djenderedjian, RH Rosenthal, MK Khani, Nov, 1227–1233
On diagnostic classification (ltr to ed). AF Kinzel, and reply of R Abrams, MA Taylor, July, 823
Efficacy of ECT in affective and schizophrenic illness. M Greenblatt, Sept, 1001–1005
On existence of dangerousness (ltr to ed). LR Doss, and reply of VR Adebimpe, July, 817–818
Hyperactivity or affective illness? (ltr to ed). ND Bowdan, March, 329
Juvenile manic-depressive illness. JH White, G O'Shanick, Sept, 1035–1036
Lithium treatment of patients with affective illness associated with organic brain symptoms. LD Young, I Taylor, V Holmstrom, Dec, 1405–1407
More "secondary mania"? (ltr to ed). J Goodwin, Dec, 1447–1448
Nontoxic hyperlithemia in impending mania. EA Wolpert, May, 580–582
Norepinephrine and 3-methoxy-4-hydroxyphenyl glycol gradients in human cerebrospinal fluid. MG Ziegler, JH Wood, CR Lake, IJ Kopin, May, 565–568
Observations on marijuana withdrawal (ltr to ed). B Teitel, May, 587
Pituitary thyrotropin response to thyrotropin-releasing hormone in affective illness: relationship to spinal fluid amine metabolites. PW Gold, FK Goodwin, T Wehr, R Rebar, Sept, 1028–1031
Psychoneuroendocrinology of affective disorder: an overview. PG Ettigi, GM Brown, May, 493–501
A question of zeal (ltr to ed). A Meisel, and reply of FG Surawicz, Oct, 1156–1157
Secondary mania? a case report. KN Wiesert, HC Hendrie, Aug, 929–930
Tempo errors and mania. J Stein, April, 454–456
Thiazide-lithium synergy in refractory mood swings. JM Himmelhoch, J Forrest, JF Neil, TP Detre, Feb, 149–152

Depression

Current social stressors and symptoms of depression. FW Ilfeld Jr, Feb, 161–166
Depression in veterans two years after Viet Nam. EP Nace, AL Meyers, CP O'Brien, N Ream, J Mintz, Feb, 167–170
EEG sleep in a child with severe depression. J Kane, P Coble, CK Conners, DJ Kupfer, July, 813–814
Effect of diet on urinary MHPG excretion in depressed patients and normal control subjects. G Muscettola, T Wehr, FR Goodwin, Aug, 914–916
Methodology in a case report (ltr to ed). RA Kuwik, and reply of G Asnis, Oct, 1158
Nuclear symptoms of schizophrenia after cingulotomy: a case report. JI Escobar, V Chandel, Nov, 1304–1306
Parkinson's disease, depression, and ECT: a review and case study. G Asnis, Feb, 191–195
Postpsychotic depression and the need for personal significance. BL MacKinnon, April, 427–429
Psychiatric illness in relatives of patients with Parkinson's disease: a preliminary report. SL Stern, HI Hurtig, J Mendels, D Balaban, April, 443–444
Psychotherapy of severe depression. S Arieti, Aug, 864–868
Retrospective audit: depressive neurosis. SD Morrison, March, 299–301
Suicide by vehicular crash. CW Schmidt Jr, JW Shaffer, HI Zlotowitz, RS Fisher, Feb, 175–178
Thyroid function and growth hormone secretion in amitriptyline-

treated depression. SB Leichter, L Kirstein, ND Martin, Nov, 1270–1272
Treatment of depression in the medically ill geriatric patient: A case report. CG Dunn, D Gross, April, 448–450
Twin relationships and depression. M Paluszny, ML Selzer, A Vinokur, L Lewandowski, Sept, 988–990

ALCOHOL, ALCOHOLISM

Alcohol and drug abuse consultation in the general hospital: a systems approach. M Galanter, TB Karasu, JF Wilder, Aug, 930–934
Dangers of minimal drinking (ltr to ed). AC Walsh, and reply of EW Massey, Sept, 1049–1050
Disulfiram toxicity and carbon disulfide poisoning. JM Rainey Jr, April, 371–378
The effect of alcohol and smoking on testosterone function and aggression in chronic alcoholics. H Persky, CP O'Brien, E Fine, WJ Howard, MA Khan, RW Beck, June, 621–625
Ethics in alcoholism research (ltr to ed). M Goldberg, and reply of H Persky, CP O'Brien, E Fine, Dec, 1447
Hydroxyzine in the treatment of alcohol withdrawal. SL Dilts, DL Keleher, G Hoge, B Haglund, Jan, 92–93
Increased sympathetic nervous system activity in alcoholic patients treated with disulfiram. CR Lake, LF Major, MG Ziegler, IJ Kipin, Dec, 1411–1413
Neurology of the "nonalcoholic" (ltr to ed). EW Massey, March, 328
The offspring of alcoholics: a critical review. E-G Nady, DR Offord, April, 357–365
Platelet MAO and alcoholism. JB Brown, Feb, 206–207
Primary and secondary benefits from treatment for alcoholism. D Edwards, S Bucky, P Coben, S Fichman, NH Berry, June, 682–683
Prognostic implications of various drinking patterns in psychiatric patients. BA Ritzler, JS Strauss, A VanOrd, FR Kokes, May, 546–549
Screening for alcoholism among college students. AR Favazza, B Cannell, Dec, 1414–1416
Side effects of simultaneous alcohol and marijuana use. A Sulkowski, L Vachon, June, 691–692
Subjects' rights, freedom of inquiry, and the future of research in the addictions. R Meyer, Aug, 899–903
Substance abuse attitude changes in medical students. JN Chappel, RD Jordan, BJ Treadway, PR Miller, April, 379–384
Ten years of change in alcoholism treatment and delivery systems. EM Pattison, March, 261–266
Ten years of inpatient programs for alcoholic patients. RA Moore, May, 542–545

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY

The American Board of Psychiatry and Neurology (off acts). Feb, 228–232; correction, April, 463–464
The American Board of Psychiatry and Neurology (off acts). July, 848–850
The American Board of Psychiatry and Neurology (off acts). Aug, 955–958
The American Board of Psychiatry and Neurology (off acts). Nov, 1332–1334
On the Boards—but gently (ltr to ed). DE Huttenback, Feb, 213–214
An examinee's perspective on Board certification. BM Brown, Nov, 1261–1264
From Board candidate to rookie examiner. MJ Napoliello, Nov, 1264–1266
A kudo for the Boards (ltr to ed). E Har-Esh, Sept, 1052
Neurology in the psychiatry Boards. BD Snyder, Nov, 1267–1269
1976 annual report of the American Board of Psychiatry and Neurology, Inc. (off acts). LH Rudy, Oct, 1207–1210
Success rates in psychiatry and neurology certification examinations. M Greenblatt, J Carew, CM Pierce, Nov, 1259–1261
On taking the child psychiatry Boards (ltr to ed). PH Davis, June, 701–702

AMERICAN JOURNAL OF PSYCHIATRY

Editing circa 1976 (editorial). FJ Braceland, Jan, 76–79
Innovation or fad? (ltr to ed). AS Rogawski, and reply of FJ Braceland, Aug, 937

AMERICAN PSYCHIATRIC ASSOCIATION

The Assembly of District Branches (off acts). April, 491–492
Collaboration between Ohio psychiatrists and the legislature to update commitment laws. VM Victoroff, July, 752–755
Commission on Certification in Administrative Psychiatry (off acts). Aug, 958
The Council on Children, Adolescents, and Their Families (off acts). VW Bernard, April, 483–484
The Council on Emerging Issues (off acts). JM Lewis, April, 485
The Council on Internal Organization (off acts). RO Pasnau, April, 488–490
The Council on International Affairs (off acts). V Bernal y Del Rio, April, 482–483
The Council on Medical Education and Career Development (off acts). RI Shader, April, 477–480
The Council on Mental Health Service (off acts). JM Stubblebine, April, 480–481
The Council on National Affairs (off acts). HM Visotsky, April, 486–488
The Council on Professions and Associations (off acts). RI Barnard, April, 484–485
The Council on Research and Development (off acts). LJ West, April, 481–482
Guidelines for psychiatrists working with the communications media (off acts). May, 609–611
Highlights of the 130th annual meeting (off acts). JH Masserman, July, 845–847
1977 annual meeting: registration and related information (off acts). March, 351–353
Patterns of Association voting behavior: I. Demographic correlates of voting/nonvoting and preference for candidates/issues. L Gurel, TW Lorei, CW Nelson, MJ Myers, Jan, 33–37
Position statement on meditation (off acts). June, 720
Position statement on the problem-oriented record-keeping system (off acts). March, 356
Position statement on the right to adequate care and treatment for the mentally ill and mentally retarded (off acts). March, 354–355
Position statement on support for psychiatric research (off acts). May, 612
Presidential address: A profession worthy of the public trust. RW Gibson, July, 723–728
Report of the Committee on Constitution and By-Laws (off acts). WH Wellborn Jr, Oct, 1206
Report of the Committee of Tellers (off acts). LF Rittelmeyer, Oct, 1203
Report of the Medical Director (off acts). M Sabshin, Oct, 1194–1199
Report of the Membership Committee (off acts). JR Elpers, Oct, 1204–1205
Report of the Secretary: summary of meetings of Board of Trustees and Executive Committee, May 1976–May 1977 (off acts). JH Masserman, Oct, 1183–1190
Report of the Speaker (off acts). IN Perr, Oct, 1200–1201
Report of the Speaker-Elect (off acts). DA Grabski, Oct, 1202
Report of the Treasurer (off acts). CB Wilkinson, Oct, 1191–1193
Response to the presidential address. J Weinberg, July, 729–730
Robert W. Gibson, M.D., one hundred and fifth president, 1976–1977. RS Garber, July, 731–735

ANHEDONIA

Anhedonia and schizophrenia. M Harrow, RR Grinker, PS Holzman, L Kayton, July, 794–797

ANNIVERSARY REACTIONS

Anniversary reactions masquerading as manic-depressive illness. JO Cavenar Jr, JL Nash, AA Maltbie, Nov, 1273–1276

ANXIETY

Anger and fear. HB Danesh, Oct, 1109–1112
A comparison of high- and low-dose lorazepam with amylobarbitone in patients with anxiety states. K Schapira, HA McClelland, DJ Newell, Jan, 25–28
Fear of the mentally ill: empirical support for the common man's response. JM Lagos, K Perlmutter, H Saexinger, Oct, 1134–1137
Is panic normal? (ltr to ed). IJ Farber, and reply of JF Heiser, D DeFrancisco, May, 588

AUDIOVISUAL TECHNIQUES

A comparison of videotaped and live patient interview examinations and written examinations in psychiatry. DH Naftulin, GH Wolkon, FA Donnelly, RW Burgoyne, FM Kline, HE Hansen, Oct, 1093–1097
Elimination of the reverse Heisenberg (Ho) effect by closed circuit television. DV Forrest, JH Ryan, P Zeidenberg, Jan, 92
Evaluation of a psychiatric clerkship by videotape. AT Meyerson, A Wachtel, J Thornton, Aug, 883–886

AUTO ACCIDENTS

Social adjustment profiles of female drivers involved in fatal and nonfatal accidents. JW Shaffer, CW Schmidt, HI Zlotowitz, RS Fisher, July, 801–804
Suicide by vehicular crash. CW Schmidt Jr, JW Shaffer, HI Zlotowitz, RS Fisher, Feb, 175–178

BEHAVIOR THERAPY

Behavior therapy in a community mental health center. RP Liberman, E Bryan III, April, 401–406
Behavior therapy in liaison psychiatry: a case report. G Middlekauff, Feb, 208–209; correction, March, 331
Patients' attitudes toward behavior therapy and psychotherapy. RB Sloane, FR Staples, K Whipple, AH Cristol, Feb, 134–137
Psychotherapies: an overview. TB Karasu, Aug, 851–863

BEREAVEMENT

Development of the Texas inventory of grief. TR Faschingbauer, RA Devaul, S Zisook, June, 696–698
A "professional will" (ltr to ed). EL Lipton, May, 585

BIOCHEMICAL STUDIES

ABO blood groups in unipolar and bipolar manic-depressive patients. RW Shapiro, OJ Rafaelsen, LP Ryder, A Svejgaard, H Sørensen, Feb, 197–200
γ-Aminobutyric acid (Gaba) and the dopamine hypothesis of schizophrenia. DP van Kammen, Feb, 138–143; correction, April, 463–464
Benzodiazepines: behavioral and neurochemical mechanisms. L Stein, JD Belluzzi, CD Wise, June, 665–669
Betel nut as a GABA blocker (ltr to ed). JR Smythies, July, 822
Blood types and affective disorders (ltr to ed). WJ Turner, and reply of RW Shapiro, OJ Rafaelsen, LP Ryder, A Svejgaard, Sept, 1053–1054
Brain mechanisms associated with therapeutic actions of benzodiazepines: focus on neurotransmitters. SH Snyder, SJ Enna, AB Young, June, 662–665
Bromocriptine in treating mania (ltr to ed). BM Saran, S Acharya, and reply of RH Gerner, RM Post, WE Bunney Jr, June, 702–703
A bufotenin-like substance in the urine of schizophrenics. AC Cottrell, MF McLeod, WR McLeod, March, 322–323
Catecholamine metabolism during heroin use. JJ Schildkraut, RE Meyer, PJ Orsulak, SM Mirin, M Roffman, PA Platz, E Grab, ME Randall, M McDougle, May, 534–537
Catecholamine metabolism in Gilles de la Tourette's syndrome. CR Lake, MG Ziegler, B Eldridge, DL Murphy, March, 257–260; correction, May, 589
Clinical implications of benzodiazepine pharmacokinetics. RI Shader, DJ Greenblatt, June, 652–656
Degraded protein-containing food and monoamine oxidase inhibitors. J Lieb, Dec, 1444–1445
Dopamine hypersensitivity and tardive dyskinesia (ltr to ed). RM Allen, and reply of GN Pandey, DL Garver, CA Tamminga, JM Davis, Oct, 1154–1155
Do tricyclic antidepressants enhance adrenergic transmission? A Frazer, J Mendels, Sept. 1040–1042
Effect of diet on urinary MHPG excretion in depressed patients and normal control subjects. G Muscettola, T Wehr, FR Goodwin, Aug, 914–916
Explaining benzodiazepines: another approach (ltr to ed). NR Cutler, D Shore, Oct, 1155
GHB and GABA (ltr to ed). F Plantey, and reply of DP van Kammen, Sept. 1045–1046
Hormones and sexual orientation in men. RC Friedman, I Dyrenfurth, D Linkie, R Tendler, JL Fleiss, May, 571–572
Increased sympathetic nervous system activity in alcoholic patients treated with disulfiram. CR Lake, LF Major, MG Ziegler, IJ Kopin, Dec, 1411–1413
In vitro half-life of ^{14}C-tryptamine in whole blood of drug-free chronic schizophrenic patients. EJ Domino, S Gahagan, Nov, 1280–1282
In vivo inhibition of platelet MAO activity by tricyclic antidepressants. JL Sullivan, C Dackis, C Stanfield, Feb, 188–190
Low levels of dopamine β-hydroxylase and psychosis. JA Ewing, RA Mueller, BA Rouse, D Silver, Aug, 927–928
Melatonin, MSH, and psychosis (ltr to ed). M Baron, and reply of JS Carman, RM Post, FK Goodwin, R Buswell, May, 583–584
Neural mechanisms of benzodiazepine actions. FH Bloom, June, 669–672
Neuroleptic drug levels and therapeutic response: preliminary observations with red blood cell bound butaperazine. DL Garver, H Dekirmenjian, JM Davis, R Casper, S Ericksen, March, 304–307
Newborn dopamine-β-hydroxylase, minor physical anomalies, and infant temperament. JL Rapoport, C Pandoni, M Renfield, CR Lake, MG Ziegler, June, 676–679
Norepinephrine and 3-methoxy-4-hydroxyphenyl glycol gradients in human cerebrospinal fluid. MG Ziegler, JH Wood, CR Lake, IJ Kopin, May, 565–568
Opiate receptor-natural ligand system: causal factor or defense system? (ltr to ed). C Torda. Aug, 935
Pituitary thyrotropin response to thyrotropin-releasing hormone in affective illness: relationship to spinal fluid amine metabolites. PW Gold, FK Goodwin, T Wehr, R Rebar, Sept, 1028–1031
Plasma testosterone in homosexual and heterosexual women. NK Gartrell, DL Loriaux, TN Chase, Oct, 1117–1119
Platelet MAO activity in schizophrenia and other psychiatric illnesses. J Sullivan, CN Stanfield, C Dackis, Oct, 1098–1103
Platelet MAO and alcoholism. JB Brown, Feb, 206–207

Platelet monoamine oxidase activity in schizophrenic patients. RE Becker, EG Shaskan, May, 512–517
Platelet monoamine oxidase in chronic schizophrenia. WH Berrettini, WH Vogel, R Clouse, July, 805–806
Postsynaptic supersensitivity in schizophrenia. GN Pandey, DL Garver, C Tamminga, S Ericksen, SI Ali, JM Davis, May, 518–522
Psychoneuroendocrinology of affective disorder: an overview. PG Ettigi, GM Brown, May, 493–501
Structural change in tardive dyskinesia (ltr to ed). J Mattes, Dec, 1448
Thyroid function and growth hormone secretion in amitriptyline-treated depression. SB Leichter, L Kirstein, ND Martin, Nov, 1270–1272
Urinary catecholamine metabolites in hyperkinetic boys treated with *d*-amphetamine. WO Shekim, H Dekirmenjian, JL Chapel, Nov, 1276–1279

BIOFEEDBACK

Biofeedback treatment of tardive dyskinesia: two case reports. H Albanese, K Gaarder, Oct, 1149–1150

BOARDING SCHOOLS

Boarding schools: effects on the mental health of Eskimo adolescents. J Kleinfeld, J Bloom, April, 411–417
Inhalant abuse in an Indian boarding school. MF Schottstaedt, JW Bjork. Nov, 1290–1293

BOOK REVIEWS, RESPONSES TO

In defense of a second edition (ltrs to ed). F Kline; H Grunebaum, Oct, 1208
An indexing question (ltr to ed). P Rubinton, and reply of S Arieti, March, 329
Kudos for review (ltr to ed). WF Cavendar, Jan, 99
Questioning a criticism (ltr to ed). J McFie, and reply of DD Daly, Dec, 1451
In response to a review (ltr to ed). J Strain, March, 330–331

BORDERLINE SYNDROME

Borderline rage and the therapist's response. T Nadelson, July, 748–751
Borderline versus narcissism (ltr to ed). H Stein, Nov, 1312–1313
Cognitive and interactive aspects of splitting. MJ Horowitz, May, 549–553
Lithium in the treatment of a child abuser. BM Panter, Dec, 1436–1437

BRIQUET'S SYNDROME

Briquet's syndrome, hysterical personality, and the MMPI. BI Liskow, P Clayton, R Woodruff, S Guze, R Cloninger, Oct, 1137–1139

CANCER

On cancer and the emotions (ltr to ed). RS Brown, and reply of FG Surawicz, May, 585

CAPGRAS SYNDROME

The Capgras syndrome as an adaptational maneuver in old age. AI Goldfarb, MB Weiner. Dec, 1434–1436

CATATONIA

Catatonia: Prediction of response to somatic treatments. R Abrams, MA Taylor, Jan, 78–80
Criteria for the diagnosis of catatonia (ltr to ed). AJ Gelenberg, and reply of R Abrams, MA Taylor, April, 462–463

CERTIFICATION

A comparison of videotaped and live patient interview examinations and written examinations in psychiatry. DH Naftulin, GH Wolkon, FA Donnelly, RW Burgoyne, FM Kline, HE Hansen, Oct, 1093–1097
Continuing education, recertification, and examination anxiety. EB Feigelson, W Frosch, Aug, 868–873
An examinee's perspective on Board certification. BM Brown, Nov, 1261–1264
From Board candidate to rookie examiner. MJ Napoliello, Nov, 1264–1266
Neurology in the psychiatry Boards. BD Snyder, Nov, 1267–1269
Success rates in psychiatry and neurology certification examinations. M Greenblatt, J Carew, CM Pierce, Nov, 1259–1261

CHILDREN AND CHILD PSYCHIATRY

Childless by choice: a clinical study. NB Kaltreider, AG Margolis, Feb, 179–182
Children's rights on entering therapeutic institutions. D Miller, RA Burt, Feb, 153–156
Chromosome variants in children with psychiatric disorders. B Say, NJ Carpenter, PR Lanier, C Banez, K Jones, JG Coldwell, April, 424–426
Coexisting childhood schizophrenia and myasthenia gravis treated successfully with neostigmine bromide. RC Schnackenberg, G Holmes, Sept, 1025–1027
A comparison of outcome in adolescent- and late-onset bipolar manic-depressive illness. Aug, 919–922
Covert maternal deprivation and pathological sucking behavior. WG Slaughter, CK Cordes, Oct, 1152–1153
Creative "restraints" (ltr to ed). MS Weiner, July, 821
EEG sleep in a child with severe depression. J Kane, P Coble, CK Conners, DJ Kupfer. July, 813–814
The effects of caffeine on reaction time in hyperkinetic and normal children. CC Reichard, ST Elder, Feb, 144–148
Ictal and subictal neurosis (ltr to ed). AD Jonas, and reply of DO Lewis, Sept, 1051–1052
Incest: children at risk. DH Browning, B Boatman, Jan, 69–72
Juvenile court versus child guidance referral: psychosocial and parental factors. SS Shanok, DO Lewis, Oct, 1030–1133
Juvenile manic-depressive illness. JH White, G O'Shanick, Sept, 1035–1036
Learning child psychiatry skills on the adult inpatient service. KS Robson, S Cerny, G Adler, A Marks, R Blacher, Jan, 56–58
Lithium in the treatment of a child abuser. BM Panter, Dec, 1436–1437
Medical histories of delinquent and nondelinquent children: an epidemiological study. DO Lewis, SS Shanok, Sept, 1020–1025; correction, Dec, 1452–1453
Mother-son folie à deux: a case of attempted patricide. LS Tucker Jr, TP Cornwall, Oct, 1146–1147
Newborn dopamine-β-hydroxylase, minor physical anomalies, and infant temperament. JL Rapoport, C Pandoni, M Renfield, CR Lake, MG Ziegler, June, 676–679
Not in the best interests of the child (ltr to ed). S Blau, and reply of AD Sorosky, Feb, 210–211
The offspring of alcoholics: a critical review. E-G Nady, DR Offord, April, 357–365
Placement and evaluation of Southeast Asian children (ltr to ed). BL Kennedy, BL Ersley, Aug, 938–939
Problems of Southeast Asian children in a refugee camp. RK Harding, JG Looney, April, 407–411
A psychodynamically oriented group training program for early childhood care givers. SI Greenspan, B Silver, MG Allen, Oct, 1104–1108
Psychopathology and mental retardation: a statistical study of 100 mentally retarded children treated at a psychiatric clinic: II. Hyperactivity. I Philips, N Williams, April, 418–419
On taking the child psychiatry Boards (ltr to ed). PH Davis, June, 701–702
Urinary catecholamine metabolites in hyperkinetic boys treated with *d*-amphetamine. WO Shekim, H Dekirmenjian, JL Chapel, Nov, 1276–1279
The use of methylphenidate and imipramine in Gilles de la Tourette's disease in children. I Fras, J Karlavage, Feb, 195–197
Vomiting during neuroleptic withdrawal in children. LE Yepes, BG Winsberg, May, 574

COGNITIVE DISTURBANCES

Cognitive and interactive aspects of splitting. MJ Horowitz, May, 549–553
Depersonalization and temporal disintegration in acute mental illness. AM Freeman III, FT Melges, June, 679–681
Temporal disorganization and inner-outer confusion in acute mental illness. FT Melges, AM Freeman III, Aug, 874–877

COLLEGE MENTAL HEALTH

Consultation in the college setting. EA Reid, May, 568–570
Screening for alcoholism among college students. AR Favazza, B Cannell, Dec, 1414–1416.

COMMUNITY CARE FACILITIES

A halfway house for mentally ill offenders. J Goldmeier, RH Sauer, VE White, Jan, 45–49
Juvenile court versus child guidance referral: psychosocial and parental factors. SS Shanok, DO Lewis, Oct, 1130–1133
Planning for a mental hospital phasedown. MP Lawton, MB Lipton, MC Fulcomer, MH Kleban, Dec, 1386–1390
Problems in analyzing the comparative costs of private versus public psychiatric care. SS Sharfstein, CA Taube, ID Goldberg, Jan, 29–32
Psychiatric illness in nursing homes (ltr to ed). R Benson, May, 587
A psychodynamically oriented group training program for early childhood care givers. SI Greenspan, S Silver, MG Allen, Oct, 1104–1108
On teaching psychotherapy in a community mental health center. JD Nason, Dec, 1419–1421

COMMUNITY MENTAL HEALTH

Behavior therapy in a community mental health center. RP Liberman, E Bryan III, April, 401–406
Consultation: what settings? (ltr to ed). AR Favazza, and reply of ZJ Lipowski, Oct, 1161–1162
In defense of community mental health. J Zusman, HR Lamb, Aug, 887–890
Planning for a mental hospital phasedown. MP Lawton, MB Lipton, MC Fulcomer, MH Kleban, Dec, 1386–1390
Psychiatric consultation: concepts and controversies. ZJ Lipowski, May, 523–528
Public and private psychiatric care (ltr to ed). WL Clovis, Sept, 1049

COMPUTERS

A computer-assisted, goal-oriented psychiatric progress note system. MJ Meldman, D Harris, RJ Pellicore, EL Johnson, Jan, 38–41
Danger of overreliance on computerized cranial tomography. EC Wells, GW Duncan, July, 811–813

CONFIDENTIALITY

Confidentiality: a solution to the problem? (ltr to ed). FJ Durgin, Aug, 939; correction, Oct, 1163
Federal constraints: earned or unearned? DT Chalkley, Aug, 911–913
The Hearst trial and confidentiality of residency records. LC Terr, Nov, 1283–1286
Informed consent and confidentiality: proposed new approaches in Illinois. R Shlensky, Dec, 1416–1418
Problems in follow-up studies. LN Robins, Aug, 904–907

CONSENT

ECT and ethical psychiatry. C Salzman, Sept, 1006–1009
Federal constraints: earned or unearned? DT Chalkley, Aug, 911–913
Informed consent and confidentiality: proposed new approaches in Illinois. R Shlensky, Dec, 1416–1418
Research barriers in psychopharmacology. JO Cole, Aug, 896–898
Tests of competency to consent to treatment. LH Roth, A Meisel, CW Lidz, March, 279–284
Toward a model of the legal doctrine of informed consent. A Meisel, LH Roth, CW Lidz, March, 285–289
Treating acute schizophrenia without drugs (ltr to ed). DA Freedman, and reply of WT Carpenter Jr, TH McGlashan, JS Strauss, June, 699–701

CONSULTATION, PSYCHIATRIC

Behavior therapy in liaison psychiatry: a case report. G Middlekauff, Feb, 208–209; correction, March, 331
Consultation in the college setting. EA Reid, May, 568–570
Consultation: what settings? (ltr to ed). AR Favazza, and reply of ZJ Lipowski, Oct, 1161–1162
The difficult defendant: a case report. HC Morgan, Nov, 1306–1307
The educational challenge of consultation-liaison psychiatry. JS Eaton, R Goldberg, E Rosinski, WS Allerton, March Supp, 20–23
The medical setting: is it beyond the psychiatrist? JJ Strain, March, 253–256
Mental health consultation in a law school clinic. RB Lacoursiere, Dec, 1422–1424
Patient progress rounds on a university hospital cardiology service. C Hollingsworth, R Hoffman, C Scalzi, B Sokol, Jan, 42–44
Pediatric bone marrow transplantation: psychosocial aspects. B Pfefferbaum, MM Lindamood, FM Wiley, Nov, 1299–1301
Problems in liaison psychiatry (ltr to ed). R Benson, and reply of JJ Strain, Sept, 1050–1051
Psychiatric consultation: concepts and controversies. ZJ Lipowski, May, 523–528
Psychiatric illness in nursing homes (ltr to ed). R Benson, May, 587
Spinal cord injury: a role for the psychiatrist. TD Stewart, May, 538–541

COPING MECHANISMS

On denying the incredible: unexplained deaths in a VA hospital. P. Kroll, KR Silk, KR Chamberlain, RJ Ging, Dec, 1376–1380
Group therapy with the terminally ill. ID Yalom, C Greaves, April, 396–400
Spinal cord injury: a role for the psychiatrist. TD Stewart, May, 538–541

COST

Cost, utilization, and utilization review of mental health services in a prepaid group practice plan. SS Goldensohn, Nov, 1222–1226
Problems in analyzing the comparative costs of private versus public psychiatric care. SS Sharfstein, CA Taube, ID Goldberg, Jan, 29–32

CRIME

Criminality and mental illness: a study of arrest rates in a rural state. JR Durbin, RA Pasewark, D Albers, Jan, 80–83
Forensic psychiatry: female offenders. M Herjanic, FA Henn, RH Vanderpearl, May, 556–558
Homicide and deinstitutionalization of the mentally ill. F Grunberg, BI Klinger, B Grumet, June, 685–687
Mother-son folie à deux: a case of attempted patricide. LS Tucker Jr, TP Cornwall, Oct, 1146–1147
Transcultural attitudes toward antisocial behavior: opinions of mental health professionals. JMA Weiss, ME Perry, Sept, 1036–1038

DEATH

Death with dignity (ltr to ed). AE Rainess, Dec, 1449
On denying the incredible: unexplained deaths in a VA hospital. P Kroll, KR Silk, KR Chamberlain, RJ Ging, Dec, 1376–1380
Emotional causes of sudden death. JE Dimsdale, Dec, 1361–1366
Group therapy with the terminally ill. ID Yalom, C Greaves, April, 396–400
Phenothiazine-induced bulbar palsy-like syndrome and sudden death. K Solomon, March, 308–311
A "professional will" (ltr to ed). EL Lipton, May, 585
Voodoo in Africa and the United States. KM Golden, Dec, 1425–1427

DELIRIUM

Acetazolamide delirium (ltr to ed). TO Rowe, May, 587–588
Rapid treatment of delirium in critically ill patients. DP Moore, Dec, 1431–1432

DELIVERY SYSTEMS, MENTAL HEALTH

Accountability, public policy, and psychiatry. AR Somers, Sept, 959–965
Brief hospitalization: a two-year follow-up. MI Herz, J Endicott, RL Spitzer, May, 502–507
Cost, utilization, and utilization review of mental health services in a prepaid group practice plan. SS Goldensohn, Nov, 1222–1226
The effects of national health insurance on Canadian psychiatry: the Ontario experience. B Liptzin, March, 248–252
Effects of payment mode on clinic attendance and rehospitalization. KL Davis, FM Estess, SC Simonton, RA Gonda, May, 576–578
Evaluation of the quality of psychiatric care for the aged. C Eisdorfer, March, 315–317
Juvenile court versus child guidance referral: psychosocial and parental factors. SS Shanok, DO Lewis, Oct, 1130–1133
Patient responsibility and the AMA discharge—a one-year follow-up study. DJ Withersty, Dec, 1442–1443
Problems in analyzing the comparative costs of private versus public psychiatric care. SS Sharfstein, CA Taube, ID Goldberg, Jan, 29–32
Public and private psychiatric care (ltr to ed). WL Clovis, Sept, 1049
Questions about rapid treatment (ltr to ed). WT Carpenter Jr, and reply of WH Anderson, JC Kuehnle, May, 584–585
The state hospital: facility of last resort. HR Lamb, Oct, 1151–1152
Ten years of change in alcoholism treatment and delivery systems. EM Pattison, March, 261–266
Ten years of inpatient programs for alcoholic patients. RA Moore, May, 542–545

DEPERSONALIZATION

Another approach to self-induced depersonalization (ltr to ed). MA Simpson, and reply of RB Kennedy, Dec, 1449–1450
Depersonalization and temporal disintegration in acute mental illness. AM Freeman III, FT Melges, June, 679–681

DIAGNOSIS

Anniversary reactions masquerading as manic-depressive illness. JO Cavenar Jr, JL Nash, AA Maltbie, Nov, 1273–1276
Atrial myxoma masquerade. RN Wharton, Dec, 1441–1442
Briquet's syndrome, hysterical personality, and the MMPI. BI Liskow, P Clayton, R Woodruff, S Guze, R Cloninger, Oct, 1137–1139
Clinical picture of atypical anorexia nervosa associated with hypothalamic tumor. JH White, P Kelly, K Dorman, March, 323–325
Criteria for the diagnosis of catatonia (ltr to ed). AJ Gelenberg, and reply of R Abrams, MA Taylor, April, 462–463
A criterion for differential diagnosis (ltr to ed). HD Zucker, March, 330
Cyclothymic disorder: validating criteria for inclusion in the bipolar affective group. HS Akiskal, AH Djenderedjian, RH Rosenthal, MK Khani, Nov, 1227–1233
Danger of overreliance on computerized cranial tomography. CE Wells, GW Duncan, July, 811–813
Diagnosis: schizophrenia versus posterior aphasia. SN Gerson, DF Benson, SH Frazier, Sept, 966–969
On diagnostic classification (ltr to ed). AF Kinzel, and reply of R Abrams, MA Taylor, July, 823
Diphenhydramine in the differential diagnosis of neuroleptic-induced oral-facial dyskinesia. BD Beitman, June, 695–696
Dysmorphophobia: symptom or disease? NC Andreasen, J Bardach, June, 673–676
Ganser-like signs in carbon monoxide encephalopathy (ltr to ed). J McEvoy, T Campbell, Dec, 1448–1449
More "secondary mania"? (ltr to ed). J Goodwin, Dec, 1447–1448
Narcolepsy and schizophrenia (ltr to ed). KC Ullman, and reply of HI Spitz, B Shapiro, July, 822
Questions about rapid treatment (ltr to ed). WT Carpenter Jr, and reply of WH Anderson, JC Kuehnle, May, 584–585
Psychiatric eclecticism: a cognitive view. J Yager, July, 736–741
Secondary mania? a case report. KN Wiesert, HC Hendrie, Aug, 929–930
Should skull films be routine? (ltr to ed). RT Rubin, Feb, 211–212
Subcategorizing Gilles de la Tourette's syndrome (ltr to ed). AK Shapiro, E Shapiro, July, 818–819
Trends in the frequency of schizophrenia by different diagnostic approaches. J Kuriansky, BJ Gurland, RL Spitzer, J Endicott, June, 631–636

DREAMS

Another way of thinking about dreams (ltr to ed). MH Hollender, and reply of M Kramer, Jan, 95–96
The brain as a dream state generator: an activation-synthesis hypothesis of the dream process. JA Hobson, RW McCarley, Dec, 1335–1348
Methodology in REM sleep studies (ltr to ed). I Maany, and reply of R Greenberg, C Pearlman, Aug, 939
The neurobiological origins of psychoanalytic dream theory. RW McCarley, JA Hobson, Nov, 1211–1221

DRUG ABUSE

Abuse of antiparkinsonian drugs by psychiatric patients. K MacVicar, July, 809–811
Angel's trumpet psychosis. RCW Hall, MK Popkin, LE McHenry, March, 312–314
Catecholamine metabolism during heroin use. JJ Schildkraut, RE Meyer, PJ Orsulak, SM Mirin, M Roffman, PA Platz, E Grab, ME Randall, M McDougle, May, 534–537
Clinical pharmacology of phencyclidine toxicity. CV Showalter, WE Thornton, Nov, 1234–1238
Depression in veterans two years after Viet Nam. EP Nace, AL Meyers, CP O'Brien, N Ream, J Mintz, Feb, 167–170
Diazepam withdrawal psychosis: a case report. MW Dysken, CH Chan, May, 573
Inhalant abuse in an Indian boarding school. MF Schottstaedt, JW Bjork, Nov, 1290–1293
More on atypical facial pain (ltr to ed). M Fishman, July, 821
Observations on marijuana withdrawal (ltr to ed). B Teitel, May, 587
Restructuring rehabilitation for women: programs for the female drug addict. KM Doyle, MA Quinones, G Tracy, D Young, J Hughes, Dec, 1395–1399
A study of low-dose amitriptyline overdoses. JP O'Brien, Jan, 66–68
Subjects' rights, freedom of inquiry, and the future of research in the addictions. R Meyer, Aug, 899–903
Substance abuse attitude changes in medical students. JN Chappel, RD Jordan, BJ Treadway, PR Miller, April, 379–384
Transcendental meditation as an alternative to heroin abuse in servicemen. DJ Anderson, Nov, 1308–1309
The treatment of drug abuse: evolution of a perspective. L Brill, Feb, 157–160
Trihexyphenidyl abuse (ltr to ed). TP Lowry: AM Rouchell, SP Dixon, Nov, 1315

DRUG INTERACTIONS

Absorption rate, blood concentrations, and early response to oral chlordiazepoxide. DJ Greenblatt, RI Shader, JS Harmatz, K Franke, J Koch-Weser, May, 559–562
Chronology of combined neuroleptics and antiparkinsonian administration (ltr to ed). A Jus, J Gautier, A Villeneuve, K Jus, P Pires, M Gagnon-Binette, Oct, 1157
Prolongation of muscle relaxant effects by lithium carbonate. FW Reimherr, MR Hodges, GE Hill, KC Wong, Feb, 205–206
Thiazide-lithium synergy in refractory mood swings. JM Himmelhoch, J Forrest, JF Neil, TP Detre, Feb, 149–152

DRUG SIDE EFFECTS

Acetazolamide delirium (ltr to ed). TO Rowe, May, 587–588
Anticholinergic psychosis in a bilingual: a case study. E Laski, E Taleporos, Sept, 1038–1040
Behavioral toxicity and equivocal suicide associated with chloroquine and its derivatives. MI Good, RI Shader, July, 798–801
Coincidental improvement in asthma during lithium treatment. SJ Nasr, RW Atkins, Sept, 1042–1043
Disulfiram toxicity and carbon disulfide poisoning. JM Rainey Jr, April, 371–378
First-degree atrioventricular block during lithium carbonate treatment. CM Jaffe, Jan, 88–89
Glaucoma due to diazepam. SW Hyams, C Keroub, April, 447–448
Increased palpebral aperture in a patient receiving amitriptyline. DJ Goode, Sept, 1043–1044
Marijuana intoxication by passive inhalation: documentation by detection of urinary metabolites. P Zeidenberg, R Bourdon, GG Nahas, Jan, 76–78
Memory loss with lithium? (ltr to ed). GF Bajor, May, 588
A middle ground in prophylactic antiparkinsonian medication (ltr to ed). DE Huttenbach, July, 820–821
More on drug-induced blurred vision (ltr to ed). AK Shapiro, Dec, 1449
Neuromuscular problems associated with lithium (ltr to ed). RP Granacher Jr, June, 702

A not so rara avis? (ltr to ed). SK Firestein, and reply of J Ananth, Dec, 1451–1452
Phenothiazine-induced bulbar palsy-like syndrome and sudden death. K Solomon, March, 308–311
Plasma nortriptyline levels and ECG findings. VE Ziegler, BT Co, JT Biggs, April, 441–443
Proven asymptomatic eosinophilia with imipramine. NR Cutler, DJ Anderson, Nov, 1296–1297
Psychotropic drug-induced bladder decompensation. JW Jefferson, April, 451–452
Psychotropics and glaucoma (ltr to ed). CL Bowden, MB Giffen, and reply of SW Hyams, C Keroub, Nov, 1314
Response to lithium in a case of L-dopa psychosis. W Braden, July, 808–809
On the safety of long-term treatment with lithium. MJ Friedman, CM Culver, RB Ferrell, Oct, 1123–1126
A second report of tricyclic-induced myoclonus (ltr to ed). S Lippmann, D Tucker, H Wagemaker, T Schulte, May, 585–586
Side effects of metronidazole (ltr to ed). AJ Giannini, March, 329–330
Side effects of simultaneous alcohol and marijuana use. A Sulkowski, L Vachon, June, 691–692
Thiazide-lithium synergy in refractory mood swings. JM Himmelhoch, J Forrest, JF Neil, TP Detre, Feb, 149–152
Timing and risk of bone marrow depression by psychotropic drugs. L DuComb, RJ Baldessarini, Nov, 1294–1295
Treating blurred vision associated with antipsychotic medication (ltr to ed). JG Carter, R Schmidt, PA Carter, Aug, 941
Tricyclic-induced myoclonus. S Lippmann, R Moskovitz, L O'Tuama, Jan, 90–91
Vomiting during neuroleptic withdrawal in children. LE Yepes, BG Winsberg, May, 574
Weight reduction in schizophrenics by molindone. G Gardos, JO Cole, March, 302–304

Extrapyramidal Symptoms

Barbiturates and tardive dyskinesia (ltr to ed). LH Lipsius, Oct, 1162–1163
Biofeedback treatment of tardive dyskinesia: two case reports. H Albanese, K Gaarder, Oct, 1149–1150
A case of oral dyskinesia associated with imipramine treatment. JJ Dekret, I Maany, TA Ramsey, J Mendels, Nov, 1297–1298
Cholinergic influences in tardive dyskinesia. CA Tamminga, RC Smith, SE Ericksen, S Chang, JM Davis, July, 769–774
Clinical research techniques in tardive dyskinesia. WE Fann, JR Stafford, RL Malone, JD Frost, BW Richman, July, 759–762
Deanol in tardive dyskinesia. KL Davis, PA Berger, LE Hollister, July, 807
Diphenhydramine in the differential diagnosis of neuroleptic-induced oral-facial dyskinesia. BD Beitman, June, 695–696
Dopamine hypersensitivity and tardive dyskinesia (ltr to ed). RM Allen, and reply of GN Pandey, DL Garver, CA Tamminga, JM Davis, Oct, 1154–1155
Dyskinesia with thiothixene. J Ananth, A Costlin, June, 689–690
The effect of benztropine mesylate in the rabbit syndrome and tardive dyskinesia. R Sovner, A Dimascio, Nov, 1301–1302
Effects of dopamine agonists in tardive dyskinesia. RC Smith, CA Tamminga, J Haraszti, GN Pandey, JM Davis, July, 763–768
Electrophysiological (H-reflex) studies of patients with tardive dyskinesia. JW Crayton, RC Smith, D Klass, S Chang, SE Ericksen, July, 775–781
An evaluation of a unique new antipsychotic agent, sulpiride: effects on serum prolactin and growth hormone levels. DH Mielke, DM Gallant, C Kessler, Dec, 1371–1375
Lithium-induced aggravation of tardive dyskinesia. EL Crews, AE Carpenter, Aug, 933
Maintenance antipsychotic dosage and tardive dyskinesia (ltr to ed). K Solomon, Nov, 1314–1315
The B-mitten EEG pattern and tardive dyskinesia: a possible association. JT Wegner, FA Struve, JM Kane, Oct, 1143–1145
More on the use of manganese in dyskinesia (ltr to ed). JP Norris, RE Sams, Dec, 1448
A not so rara avis? (ltr to ed). SK Firestein, and reply of J Ananth, Dec, 1451–1452
Paradoxical response to dopamine agonists in tardive dyskinesia. BJ Carroll, GC Curtis, E Kokmen, July, 785–789
The prevention of tardive dyskinesia. GE Crane, July, 756–758
The relationship between parkinsonism and tardive dyskinesia. J Gerlach, July, 781–784
In response to a response (ltr to ed). MH Branchey, GM Simpson, Feb, 211
Reversible tardive dyskinesia? (ltr to ed). RJ Ursano, and reply of F Quitkin, A Rifkin, D Klein, June, 703–704
Structural change in tardive dyskinesia (ltr to ed). J Mattes, Dec, 1448
A survey of tardive dyskinesia in psychiatric outpatients. GM Asnis, MA Leopold, RC Duvoisin, AH Schwartz, Dec, 1367–1370
Tardive dyskinesia: are first signs reversible? F Quitkin, A Rifkin, L Gochfeld, DF Klein, Jan, 84–87
Tardive dyskinesia in young adults. D Tarsy, R Granacher, M Bralower, Sept, 1032–1034

DRUG TREATMENT PROGRAMS

Methadone maintenance in a patient on chronic hemodialysis. WM Glazer, GL Cohn, Aug, 931–932
Restructuring rehabilitation for women: programs for the female drug addict. KM Doyle, MA Quinones, G Tracy, D Young, J Hughes, Dec, 1395–1399
Transcendental meditation as an alternative to heroin abuse in servicemen. DJ Anderson, Nov, 1308–1309
The use of nicotine gum during cessation of smoking. NG Schneider, P Popek, ME Jarvik, ER Gritz, April, 439–440

DRUGS, RESEARCH AND USE

General

Psychotherapy and pharmacotherapy: conceptual issues. JP Docherty, SR Marder, DP van Kammen, SG Siris, May, 529–533
Psychotropic drug-induced bladder decompensation. JW Jefferson, April, 451–452
The relationship between parkinsonism and tardive dyskinesia. J Gerlach, July, 781–784
Research barriers in psychopharmacology. JO Cole, Aug, 896–898
Treating acute schizophrenia without drugs (ltrs to ed). DP Moore; R Benson, and reply of WT Carpenter Jr, TH McGlashan, JS Strauss, June, 699–701
The treatment of acute schizophrenia without drugs: an investigation of some current assumptions. WT Carpenter Jr, TH McGlashan, JS Strauss, Jan, 14–20

Antianxiety Agents

Absorption rate, blood concentrations, and early response to oral chlordiazepoxide. DJ Greenblatt, RI Shader, JS Harmatz, K Franke, J Koch-Weser, May, 559–562
Benzodiazepines: behavioral and neurochemical mechanisms. L Stein, JD Belluzzi, CD Wise, June, 665–669
Brain mechanisms associated with therapeutic actions of benzodiazepines: focus on neurotransmitters. SH Snyder, SJ Enna, AB Young, June, 662–665
Clinical implications of benzodiazepine pharmacokinetics. RK Shader, DJ Greenblatt, June, 652–656
A comparison of high- and low-dose lorazepam with amylobarbitone in patients with anxiety states. K Schapira, HA McClelland, DJ Newell, Jan, 25–28
Diazepam withdrawal psychosis: a case report. MW Dysken, CH Chan, May, 573
Evaluating antianxiety agents in humans: experimental paradigms. EH Uhlenhuth, June, 659–662

Explaining benzodiazepines: another approach (ltr to ed). NR Cutler, D Shore, Oct, 1155
Glaucoma due to diazepam. SW Hyams, C Keroub, April, 447–448
Hydroxyzine in the treatment of alcohol withdrawal. SL Dilts, DL Keleher, G Hoge, B Haglund, Jan, 92–93
Neural mechanisms of benzodiazepine actions. FH Bloom, June, 669–672
Psychotropics and glaucoma (ltr to ed). CL Bowden, MB Giffen, and reply of SW Hyams, C Keroub, Nov, 1314
The role of benzodiazepines in nonpsychiatric medical practice. L Lasagna, June, 656–658

Antidepressants

Amitriptyline therapy in anorexia nervosa. DC Moore, Nov, 1303–1304
A case of oral dyskinesia associated with imipramine treatment. JJ Dekret, I Maany, TA Ramsey, J Mendels, Nov, 1297–1298
Degraded protein-containing food and monoamine oxidase inhibitors. J Lieb, Dec, 1444–1445
Do tricyclic antidepressants enhance adrenergic transmission? A Frazer, J Mendels, Sept, 1040–1042
Increased palpebral aperture in a patient receiving amitriptyline. DJ Goode, Sept, 1043–1044
In vivo inhibition of platelet MAO activity by tricyclic antidepressants. JL Sullivan, C Dackis, C Stanfield, Feb, 188–190
Overdosing the tricyclic overdose patient (ltr to ed). JT Biggs, RA Riesenberg, VE Ziegler, and replies of RA Munoz; PC Holinger, HL Klawans, April, 461–462
Plasma nortriptyline levels and ECG findings. VE Ziegler, BT Co, JT Biggs, April, 441–443
Protriptyline: an effective agent in the treatment of the narcolepsy-cataplexy syndrome and hypersomnia. HS Schmidt, RW Clark, PR Hyman, Feb, 183–185
Proven asymptomatic eosinophilia with imipramine. NR Cutler, DJ Anderson, Nov, 1296–1297
Relationship between age and tricyclic antidepressant plasma levels. A Nies, DS Robinson, MJ Friedman, R Green, TB Cooper, CL Ravaris, JO Ives, July, 790–793
A second report of tricyclic-induced myoclonus (ltr to ed). S Lippmann, D Tucker, H Wagemaker, T Schulte, May, 585–586
A study of low-dose amitriptyline overdoses. JP O'Brien, Jan, 66–68
Thyroid function and growth hormone secretion in amitriptyline-treated depression. SB Leichter, L Kirstein, ND Martin, Nov, 1270–1272
Tricyclic choice for ill elderly patients (ltr to ed). DR Weinberger, and reply of DG Dunn, D Gross, Sept, 1048–1049
Tricyclic-induced myoclonus. S Lippman, R Moskovitz, L O'Tuama, Jan, 90–91
The use of methylphenidate and imipramine in Gilles de la Tourette's disease in children. I Fras, J Karlavage, Feb, 195–197

Antiparkinsonian Agents

Abuse of antiparkinsonian drugs by psychiatric patients. K MacVicar, July, 809–811
Chronology of combined neuroleptics and antiparkinsonian administration (ltr to ed). A Jus, J Gautier, A Villeneuve, K Jus, P Pires, M Gagnon-Binette, Oct, 1157
The effect of benztropine mesylate in the rabbit syndrome and tardive dyskinesia. R Sovner, A DiMascio, Nov, 1301–1302
A middle ground in prophylactic antiparkinsonian medication (ltr to ed). DE Huttenbach, July, 820–821
Response to lithium in a case of L-dopa psychosis. W Braden, July, 808–809
Trihexyphenidyl abuse (ltr to ed). TP Lowry, AM Rouchell, SP Dixon, Nov, 1315

Antipsychotic Agents

Chronology of combined neuroleptics and antiparkinsonian administration (ltr to ed). A Jus, J Gautier, A Villeneuve, K Jus, P Pires, M Gagnon-Binette, Oct, 1157
Dyskinesia with thiothixene. J Ananth, A Costin, June, 689–690
The effect of low-cost maintenance medication on the rehospitalization of schizophrenic outpatients. J Cody, AM Robinson, Jan, 73–76
An evaluation of a unique new antipsychotic agent, sulpiride: effects on serum prolactin and growth hormone levels. DH Mielke, DM Gallant, C Kessler, Dec, 1371–1375
Fluphenazine decanoate during pregnancy. MF Cleary, July, 815–816
Improvement or relief from side effects? (ltr to ed). JM Kane, and reply of WT Carpenter Jr, TH McGlashan, JS Strauss, July, 819–820
Maintenance antipsychotic dosage and tardive dyskinesia (ltr to ed). K Solomon, Nov, 1314–1315
A middle ground in prophylactic antiparkinsonian medication (ltr to ed). DE Huttenbach, July, 820–821
More on drug-induced blurred vision (ltr to ed). AK Shapiro, Dec, 1449
Neuroleptic drug levels and therapeutic response: preliminary observations with red blood cell bound butaperazine. DL Garver, H Dekirmenjian, JM Davis, R Casper, S Ericksen, March, 304–307
A not so rara avis? (ltr to ed). SK Firestein, and reply of J Ananth, Dec, 1451–1452
Outpatient treatment of schizophrenia. N Hansell, GL Willis, Oct, 1082–1086
Phenothiazine-induced bulbar palsy-like syndrome and sudden death. K Solomon, March, 308–311
The prevention of tardive dyskinesia. GE Crane, July, 756–758
Priapism and phenothiazine: a case report of the association of priapism and mesoridazine therapy. JI Gottlieb, T Lustberg, Dec, 1445–1446
The relationship between parkinsonism and tardive dyskinesia. J Gerlach, July, 781–784
Structural change in tardive dyskinesia (ltr to ed). J Mattes, Dec, 1448
Tardive dyskinesia: are first signs reversible? F Quitkin, A Rifkin, L Gochfeld, DF Klein, Jan, 84–87
Timing and risk of bone marrow depression by psychotropic drugs. L DuComb, RJ Baldessarini, Nov, 1294–1295
Treating blurred vision associated with antipsychotic medication (ltr to ed). JG Carter, R Schmidt, PA Carter, Aug, 941
The treatment of acute schizophrenia without drugs: an investigation of some current assumptions. WT Carpenter Jr, TH McGlashan, JS Strauss, Jan, 14–20
Vomiting during neuroleptic withdrawal in children. LE Yepes, BG Winsberg, May, 574
Weight reduction in schizophrenics by molindone. G Gardos, JO Cole, March, 302–304

Arecaidine

Betel nut as a GABA blocker (ltr to ed). JR Smythies, July, 822

Baclofen

Baclofen treatment in chronic schizophrenia: a clinical trial. LB Bigelow, H Nasrallah, J Carman, JC Gillin, RJ Wyatt, March, 318–320

Bromocriptine

Bromocriptine in treating mania (ltr to ed). BM Saran, S Acharya, and reply of RH Gerner, RM Post, WE Bunney Jr, June, 702–703

Chloroquine

Behavioral toxicity and equivocal suicide associated with chloroquine and its derivatives. MI Good, RK Shader, July, 798–801

Cholinergic Agents

Cholinergic influences in tardive dyskinesia. CA Tamminga, RC Smith, SE Ericksen, S Chang, JM Davis, July, 769–774

Diphenhydramine

Diphenhydramine in the differential diagnosis of neuroleptic-induced oral-facial dyskinesia. BD Beitman, June, 695–696

Disulfiram

Disulfiram toxicity and carbon disulfide poisoning. JM Rainey Jr, April, 371–378
Increased sympathetic nervous system activity in alcoholic patients treated with disulfiram. CR Lake, LF Major, MG Ziegler, IJ Kopin, Dec, 1411–1413
Low levels of dopamine β-hydroxylase and psychosis. JA Ewing, RA Mueller, BA Rouse, D Silver, Aug, 927–928

Dopamine Agonists

Effects of dopamine agonists in tardive dyskinesia. RC Smith, CA Tamminga, J Haraszti, GN Pandey, JM Davis, July, 763–768
Paradoxical response to dopamine agonists in tardive dyskinesia. BJ Carroll, GC Curtis, E Kokmen, July, 785–789

Glyceryl Trinitrate

Impotence responsive to glyceryl trinitrate. JW Mudd, Aug, 922–925; correction, Nov, 1315

Lithium

Coincidental improvement in asthma during lithium treatment. SJ Nasr, RW Atkins, Sept, 1042–1043
A computer-based lithium library (ltr to ed). JW Jefferson, JH Greist, Sept, 1049
First-degree atrioventricular block during lithium carbonate treatment. CM Jaffe, Jan, 88–89
Hyperactivity or affective illness? (ltr to ed). ND Bowdan, March, 329
In response to a response (ltr to ed). MH Branchey, GM Simpson, Feb, 211
Lithium-induced aggravation of tardive dyskinesia. EL Crews, AE Carpenter, Aug, 933
Lithium in the treatment of a child abuser. BM Panter, Dec, 1436–1437
Lithium treatment of patients with affective illness associated with organic brain symptoms. LD Young, I Taylor, V Holmstrom, Dec, 1405–1407
Memory loss with lithium? (ltr to ed). GF Bajor, May, 588
Memory loss with lithium treatment (ltr to ed). D Preodor, GY Wolpert, D Ostrow, P Holinger, EA Wolpert, Sept, 1047–1048
Neuromuscular problems associated with lithium (ltr to ed). RP Grancher Jr, June, 702
Nontoxic hyperlithemia in impending mania. EA Wolpert, May, 580–582
On placebo effects (ltr to ed). BE Green, and reply of MH Sheard, JL Marini, Aug, 935–936
On the safety of long-term treatment with lithium. MJ Friedman, CM Culver, RB Ferrell, Oct, 1123–1126
Prolongation of muscle relaxant effects by lithium carbonate. FW Reimherr, MR Hodges, GE Hill, KC Wong, Feb, 205–206
Response to lithium in a case of L-dopa psychosis. W Braden, July, 808–809
Thiazide-lithium synergy in refractory mood swings. JM Himmelhoch, J Forrest, JF Neil, TP Detre, Feb, 149–152

Manganese Chelate

More on the use of manganese in dyskinesia (ltr to ed). JP Norris, RE Sams, Dec, 1448

Methadone

Methadone maintenance in a patient on chronic hemodialysis. WM Glazer, GL Cohn, Aug, 931–932

Metronidazole

Side effects of metronidazole (ltr to ed). AJ Giannini, March, 329–330

Muscle Relaxants

Prolongation of muscle relaxant effects by lithium carbonate. FW Reimherr, MR Hodges, GE Hill, KC Wong, Feb, 205–206

Narcotic Antagonists

Lack of effect of naloxone on schizophrenic symptoms. DS Janowsky, DS Segal, F Bloom, A Abrams, R Guillemin, Aug, 926–927
The treatment of perceptual disturbances in schizophrenia with naloxone hydrochloride. AA Kurland, L McCabe, TE Hanlon, D Sullivan, Dec, 1408–1410
The use of an oral opiate antagonist in chronic schizophrenic patients: a pilot study. DH Mielke, DM Gallant, Dec, 1430–1431

Neostigmine Bromide

Coexisting childhood schizophrenia and myasthenia gravis treated successfully with neostigmine bromide. RC Schnackenberg, G Holmes, Sept, 1025–1027

Phenytoin

Phenytoin treatment of the binge-eating syndrome. BM Wermuth, KL Davis, LE Hollister, AJ Stunkard, Nov, 1249–1253

Physostigmine

Overdosing the tricyclic overdose patient (ltr to ed). JT Biggs, RA Riesenberg, VE Ziegler, and replies of RA Munoz; PC Holinger, HL Klawans, April, 461–462

Sedatives

Barbiturates and tardive dyskinesia (ltr to ed). LH Lipsius, Oct, 1162–1163

Stimulants

Deanol in tardive dyskinesia. KL Davis, PA Berger, LE Hollister, July, 807
The effects of caffeine on reaction time in hyperkinetic and normal children. CC Reichard, ST Elder, Feb, 144–148
The use of methylphenidate and imipramine in Gilles de la Tourette's disease in children. I Fras, J Karlavage, Feb, 195–197

THC (Marijuana, Hashish)

Elimination of the reverse Heisenberg (Ho) effect by closed-circuit television. DV Forrest, JH Ryan, P Zeidenberg, Jan, 92
Marijuana intoxication by passive inhalation: documentation by detection of urinary metabolites. P Zeidenberg, R Bourdon, GG Nahas, Jan, 76–78
Side effects of simultaneous alcohol and marijuana use. A Sulkowski, L Vachon, June, 691–692

L-Tryptophan

Availability of L-tryptophan (ltr to ed). RH Bridenbaugh, JG Lafft, and reply of E Hartmann, Nov, 1311–1312
L-Tryptophan in obsessive-compulsive disorders. JA Yaryura-Tobias, HN Bhagavan, Nov, 1298–1299
L-Tryptophan: a rational hypnotic with clinical potential. E Hartmann, April, 366–370; correction, June, 704

DYSMORPHOPHOBIA

Dysmorphophobia: symptom or disease? NC Andreasen, J Bardach, June, 673–676
A neglected reference (ltr to ed). K Nakdimen, and reply of NC Andreasen, Nov, 1313–1314

EATING DISORDERS

Amitriptyline therapy in anorexia nervosa. DC Moore, Nov, 1303–1304
Clinical picture of atypical anorexia nervosa associated with hypothalamic tumor. JH White, P Kelly, K Dorman, March, 323–325
On the course of anorexia nervosa. RC Casper, JM Davis, Sept, 974–978
A misinterpretation? (ltr to ed). RS Kalucy, TRE Pilkington, AH Crisp, and reply of MJ Mills, AJ Stunkard, April, 459–460
Phenytoin treatment of the binge-eating syndrome. BM Wermuth, KL Davis, LE Hollister, AJ Stunkard, Nov, 1249–1253
A reminder of earlier work (ltr to ed). L Tec, Jan, 98
Substance abuse attitude changes in medical students. JN Chappel, RD Jordan, BJ Treadway, PR Miller, April, 379–384

ECT

Current perspectives on ECT: a discussion. FH Frankel, Sept, 1014–1019
ECT and ethical psychiatry. C Salzman, Sept, 1006–1009
ECT and memory loss. LR Squire, Sept, 997–1001
Efficacy of ECT in affective and schizophrenic illness. M Greenblatt, Sept, 1001–1005
Methodology in a case report (ltr to ed). RA Kuwik, and reply of G Asnis, Oct, 1158
Myths of "shock therapy." M Fink, Sept, 991–996
Shock treatment, brain damage, and memory loss: a neurological perspective. J Friedberg, Sept, 1010–1014

EDITORIALS

A word of appreciation (editorial). FJ Braceland, Jan, 63–65

EDUCATION, MEDICAL

Challenging the medical student in a psychiatry clerkship. LS Linet, Jan, 53–55
Dehumanization in medical education (ltr to ed). EM Stein, and reply of PJ Fink, Aug, 937–938
Medical student education in psychiatry. DG Langsley, AM Freedman, M Haas, JH Grubbs, March Supp, 15–20
Patient progress rounds on a university hospital cardiology service. C Hollingsworth, R Hoffman, C Scalzi, B Sokol, Jan, 42–44
The relationship of psychiatry to primary care. PJ Fink, Feb, 126–129
Teaching psychological medicine to family practice residents. ER Smarr, R Berkow, Sept, 984–987

EDUCATION, PSYCHIATRIC

Challenging the medical student in a psychiatry clerkship. LS Linet, Jan, 53–55
Challenging the psychiatric education establishment (ltr to ed). B Liptzin, and reply of LS Linet, Aug, 940–941
Characteristics of psychiatric residency programs and quality of education. RS Daniels, AS Abraham, R Garcia, C Wilkinson, March Supp, 7–10
On competency-based models (ltr to ed). MF Heiman, and reply of HM Weinstein, ML Russell, April, 460–461
A computer-assisted, goal-oriented psychiatric progress note system. MJ Meldman, D Harris, RJ Pellicore, EL Johnson, Jan, 38–41
Continuing education, recertification, and examination anxiety. EB Feigelson, W Frosch, Aug, 869–873
The educational challenge of consultation-liaison psychiatry. JS Eaton Jr, R Goldberg, E Rosinski, WS Allerton, March Supp, 20–23
The emotionally disturbed psychiatric resident. AT Russell, RO Pasnau, AC Taintor, Jan, 59–62
Evaluation of a psychiatric clerkship by videotape. AT Meyerson, A Wachtel, J Thornton, Aug, 883–886
An examination of the federal psychiatric training grant peer review process. CB Wilkinson, VI Reus, June, 637–641
An examinee's perspective on Board certification. BM Brown, Nov, 1261–1264
Focused psychiatric curriculum selection: student, psychiatrist, and nonpsychiatrist physician expectations. W Johnson, J Snibbe, K Hoffman, L Evans, Oct, 1126–1130
From Board candidate to rookie examiner. MJ Napoliello, Nov, 1264–1266
Governmental peer review of training programs in child psychiatry. LB Silver, R Brunstetter, D Renshaw, JP Comer, March Supp, 11–14
The Hearst trial and the confidentiality of residency records. LC Terr, Nov, 1283–1286
Introduction. BS Brown, March Supp, 1
Learning child psychiatry skills on the adult inpatient service. KS Robson, S Cerny, G Adler, A Marks, R Blacher, Jan, 56–58
The life cycle and psychiatric education (ltr to ed). RN Butler, and reply of JS Eaton Jr, Oct, 1157–1158
Medical student education in psychiatry. DG Langsley, AM Freedman, M Haas, JH Grubbs, March Supp, 15–20
Neurology in the psychiatry Boards. BD Snyder, Nov, 1267–1269
Patient progress rounds on a university hospital cardiology service. C Hollingsworth, R Hoffman, C Scalzi, B Sokol, Jan, 42–44
Postscript. FN Waldrop, March Supp, 29
Problems for women in psychiatric residency. EP Benedek, G Barton, C Bieniek, Nov, 1244–1248
Psychiatric eclecticism: a cognitive view. J Yager, July, 736–741
Psychiatric education: state of the art, 1976. JS Eaton Jr, RS Daniels, H Pardes, March Supp, 2–6
Research training in psychiatry. H Pardes, AM Freedman, V Reus, March Supp, 24–28
On residency: emotions and spouses' involvement (ltr to ed). JC Goetzl, U Goetzl; DP Miley, BJ Conn, and reply of AT Russell, Oct, 1155–1156
A role for medical ethics in postgraduate psychiatry courses? M Jellinek, D Parmelee, Dec, 1438–1439
Substance abuse attitude changes in medical students. JN Chappel, RD Jordan, BJ Treadway, PR Miller, April, 379–384
Success rates in psychiatry and neurology certification examinations. M Greenblatt, J Carew, CM Pierce, Nov, 1259–1261
Teaching psychological medicine to family practice residents. ER Smarr, R Berkow, Sept, 984–987
On teaching psychotherapy in a community mental health center. JD Nason, Dec, 1419–1421

EEG

EEG sleep in a child with severe depression. J Kane, P Coble, CK Conners, DJ Kupfer, July, 813–814
The B-mitten EEG pattern and tardive dyskinesia: a possible association. JT Wegner, FA Struve, JM Kane, Oct, 1143–1145

EMOTION

Emotional causes of sudden death. JE Dimsdale, Dec, 1361–1366

EMPLOYMENT AND CAREER

Attitudes toward parenting in dual-career families. CL Johnson, FA Johnson, April, 391–395
Some effects of the new feminism. R Moulton, Jan, 1–6
The successful professional woman: on being married to one. T Nadelson, L Eisenberg, Oct, 1071–1076

EPIDEMIOLOGY

Medical histories of delinquent and nondelinquent children: an epidemiological study. DO Lewis, SS Shanok, Sept, 1020–1025; correction, Dec, 1452–1453
Trends in the frequency of schizophrenia by different diagnostic approaches. J Kuriansky, BJ Gurland, RL Spitzer, J Endicott, June, 631–636

EPILEPSY

Ictal and subictal neurosis (ltr to ed). AD Jonas, and reply of DO Lewis, Sept, 1051–1052
Rapidly recurring seizures of psychogenic origin. KP Poulose, AA Shaw, Oct, 1145–1146

EROTOMANIA

Erotomanic delusions in a mentally retarded patient. B Greyson, S Akhtar, March, 325–326

EST

Psychiatric disturbances associated with Erhard Seminars Training: I. A report of cases. LL Glass, MA Kirsch, FN Parris, March, 245–247
Psychiatric disturbances associated with Erhard Seminars Training: II. Additional cases and theoretical considerations. MA Kirsch, LL Glass, Nov, 1254–1258
Research in est? (ltr to ed). ID Yalom, and reply of RW Fuller, Feb, 213

ETHICS

An answer to "a question of ethics" (ltr to ed). EF Kal, Feb, 212
Contractual agreements with adolescents? (ltr to ed). S Smith, and reply of D Miller, Oct, 1160–1161
ECT and ethical psychiatry. C Salzman, Sept, 1006–1009
Ethics in alcoholism research (ltr to ed). M Goldberg, and reply of H Persky, CP O'Brien, E Fine, Dec, 1447
The ethics of practice in adolescent psychiatry. D Miller, April, 420–424
John Stuart Mill on the liberty of the mentally ill: a historical note. J Monahan, Dec, 1428–1429
Moral therapy and the problem of morale. L Sederer, March, 267–272
Peer review and professional ethics. F Sullivan, Feb, 186–188
Restraints in delirium tremens (ltr to ed). F Winston, Jan, 98
A role for medical ethics in postgraduate psychiatry courses? M Jellinek, D Parmelee, Dec, 1438–1439

FAMILY PROCESSES AND FAMILY THERAPY

Attitudes toward parenting in dual-career families. CL Johnson, FA Johnson, April, 391–395
Childless by choice: a clinical study. NB Kaltreider, AG Margolis, Feb, 179–182
Community psychiatry in Tutuila, American Samoa. WE Walters, Aug, 917–919
Covert maternal deprivation and pathological sucking behavior. WG Slaughter, CK Cordes, Oct, 1152–1153
Death with dignity (ltr to ed). AE Rainess, Dec, 1449
Episodic dyscontrol and family dynamics. HT Harbin, Oct, 1113–1116
Family involvement on a psychiatric inpatient service. DJ Withersty, Jan, 93–94
Fatherhood and emotional illness. JO Cavenar Jr, NT Butts, April, 429–431
Incest: children at risk. DH Browning, B Boatman, Jan, 69–72
Juvenile court versus child guidance referral: psychosocial and parental factors. SS Shanok, DO Lewis, Oct, 1130–1133
Learning child psychiatry skills on the adult inpatient service. KS Robson, S Cerny, G Adler, A Marks, R Blacher, Jan, 56–58
Mother-son folie à deux: a case of attempted patricide. LS Tucker Jr, TP Cornwall, Oct, 1146–1147
The multiple family group as a small society: family regulation of interaction with nonmembers. D Reiss, R Costell, Jan, 21–24
The offspring of alcoholics: a critical review. E-G Nady, DR Offord, April, 357–365
Problems of Southeast Asian children in a refugee camp. RK Harding, JG Looney, April, 407–411

FEES

The effect of low-cost maintenance medication on the rehospitalization of schizophrenic outpatients. J Cody, AM Robinson, Jan, 73–76
Effects of payment mode on clinic attendance and rehospitalization. KL Davis, FM Estess, SC Simonton, RA Gonda, May, 576–578
More on "free" psychotherapy (ltr to ed). SL Debow, and reply of J Paris, May, 588–589

FOLIE À DEUX

Mother-son folie à deux: a case of attempted patricide. LS Tucker Jr, TP Cornwall, Oct, 1146–1147

FOLLOW-UP STUDIES

Asylums revisited. R Peele, PV Luisada, MJ Lucas, D Rudisell, D Taylor, Oct, 1077–1081
Brief hospitalization: a two-year follow-up. MI Herz, J Endicott, RL Spitzer, May, 502–507
Kidney donors revisited: JR Marshall, CH Fellner, May, 575–576
Lawyers' use of psychiatry: II. EP Benedek, ML Selzer, April, 435–436
Patient responsibility and the AMA discharge—a one-year follow-up study. DJ Withersty, Dec, 1442–1444
Problems in follow-up studies. LN Robins, Aug, 904–907
Trends in the frequency of schizophrenia by different diagnostic approaches. J Kuriansky, BJ Gurland, RL Spitzer, J Endicott, June, 631–636

FORENSIC PSYCHIATRY

Changing law and clinical dilemmas. WD Weitzel, March, 293–295
Children's rights on entering therapeutic institutions. D Miller, RA Burt, Feb, 153–156

Collaboration between Ohio psychiatrists and the legislature to update commitment laws. VM Victoroff, July, 752–755
Committing violent manic patients (ltr to ed). FG Surawicz, June, 704
Contractual agreements with adolescents? (ltr to ed). S Smith, and reply of D Miller, Oct, 1160–1161
Creative "restraints" (ltr to ed). MS Weiner, July, 821
Criminal law: implications for psychiatry? (ltr to ed). HL Hartman, Oct, 1162
Dangerousness, confidentiality, and the duty to warn. LH Roth, A Meisel, May, 508–511
The difficult defendant: a case report. HC Morgan, Nov, 1306–1307
ECT and ethical psychiatry. C Salzman, Sept, 1006–1009
On existence of dangerousness (ltr to ed). LR Doss, and reply of VR Adebimpe, July, 817–818
Federal constraints: earned or unearned? DT Chalkley, Aug, 911–913
Forensic psychiatry: female offenders. M Herjanic, FA Henn, RH Vanderpearl, May, 556–558
Freedom of inquiry and subjects' rights: an introduction. D Reiss, Aug, 891–892
A halfway house for mentally ill offenders. J Goldmeier, RH Sauer, EV White, Jan, 45–49
The Hearst trial and the confidentiality of residency records. LC Terr, Nov, 1283–1286
Informed consent and confidentiality: proposed new approaches in Illinois. R Shlensky, Dec, 1416–1418
John Stuart Mill on the liberty of the mentally ill: a historical note. J Monahan, Dec, 1428–1429
Lawyers' use of psychiatry: II. EP Benedek, ML Selzer, April, 435–436
Motivations for drug treatment (ltr to ed). RB Fisher, and reply of RJ Harford, Sept, 1046–1047
Physical violence in the concept of dangerousness: a case report. VR Adebimpe, Feb, 203–204
A question of zeal (ltr to ed). A Meisel, and reply of FG Surawicz, Oct, 1156–1157
Recent mental health litigation: a critical perspective. AA Stone, March, 273–279
Social discrediting of psychiatry: the protasis of legal disfranchisement. PE Dietz, Dec, 1356–1360
Tarasoff: protective privilege versus public peril. H Gurevitz, March, 289–292
Tests of competency to consent to treatment. LH Roth, A Meisel, CW Lidz, March, 279–284
Toward a model of the legal doctrine of informed consent. A Meisel, LH Roth, CW Lidz, March, 285–289

GANSER SYNDROME

Ganser-like signs in carbon monoxide encephalopathy (ltr to ed). J McEvoy, T Campbell, Dec, 1448–1449
The Ganser syndrome in an adolescent Hispanic-black female. TJ Nardi, WJ Di Scipio, April, 453–454

GENETIC STUDIES

Chromosome variants in children with psychiatric disorders. B Say, NJ Carpenter, PR Lanier, C Banez, K Jones, JG Coldwell, April, 424–426
More on genetic transmission in schizophrenia (ltr to ed). MA Taylor, R Abrams, and reply of SS Kety, April, 457–458
Paranoid schizophrenia in a 47,XYY male. E Dorus, W Dorus, MA Telfer, June, 687–689
Psychiatric illness in relatives of patients with Parkinson's disease: a preliminary report. SL Stern, HI Hurtig, J Mendels, D Balaban, April, 443–444

GERIATRIC PSYCHIATRY

The Capgras syndrome as an adaptational maneuver in old age. AI Goldfarb, MB Weiner, Dec, 1434–1436
Evaluation of the quality of psychiatric care for the aged. C Eisdorfer, March, 315–317
The life cycle and psychiatric education (ltr to ed). RN Butler, and reply of JS Eaton Jr, Oct, 1157–1158
Psychiatric illness in nursing homes (ltr to ed). R Benson, May, 587
Relationship between age and tricyclic antidepressant plasma levels. A Nies, DS Robinson, MJ Friedman, R Green, TB Cooper, CL Ravaris, JO Ives, July, 790–793
Treatment of depression in the medically ill geriatric patient: a case report. CG Dunn, D Gross, April, 448–450
Tricyclic choice for ill elderly patients (ltr to ed). DR Weinberger, and reply of DG Dunn, D Gross, Sept, 1048–1049

GILLES DE LA TOURETTE'S SYNDROME

Alternative drug treatments in Gilles de la Tourette's syndrome (ltrs to ed). EG Lutz; J Feldman, Jan, 98–99
Catecholamine metabolism in Gilles de la Tourette's syndrome. CR Lake, MG Ziegler, B Eldridge, DL Murphy, March, 257–260; correction, May, 589
Subcategorizing Gilles de la Tourette's syndrome (ltr to ed). AK Shapiro, E Shapiro, July, 818–819
The use of methylphenidate and imipramine in Gilles de la Tourette's disease in children. I Fras, J Karlavage, Feb, 195–197

GROUP THERAPY AND GROUP PROCESSES

Group therapy with the terminally ill. ID Yalom, C Greaves, April, 396–400
The multiple group as a small society: family regulation of interaction with nonmembers. D Reiss, R Costell, Jan, 21–24
Psychiatric disturbances associated with Erhard Seminars Training: I. A report of cases. LL Glass, MA Kirsch, FN Parris, March, 245–247
Psychiatric disturbances associated with Erhard Seminars Training: II. Additional cases and theoretical considerations. MA Kirsch, LL Glass, Nov, 1254–1258
A psychodynamically oriented group training program for early childhood care givers. SI Greenspan, B Silver, MG Allen, Oct, 1104–1108
Research in est? (ltr to ed). ID Yalom, and reply of RW Fuller, Feb, 213
Voluntary and involuntary treatment of aggressive patients. DJ Madden, May, 553–555
Whom to refer for group psychotherapy. H Grunebaum, W Kates, Feb, 130–133

HEMODIALYSIS

Can dialysis help the chronic schizophrenic? (ltr to ed). WW Weddington Jr, GN Ferris; NB Levy, and reply of H Wagemaker, Nov, 1310–1311
Methadone maintenance in a patient on chronic hemodialysis. WM Glazer, GL Cohn, Aug, 931–932
The use of hemodialysis in chronic schizophrenia. H Wagemaker Jr, R Cade, June, 684–685

HISTORY

Freedom of inquiry and subjects' rights: historical perspective. D Musto, Aug, 893–896

Images of the mind: psychiatry and the commercial film. I Schneider, June, 613–620
John Stuart Mill on the liberty of the mentally ill: a historical note. J Monahan, Dec, 1428–1429
Moral therapy and the problem of morale. L Sederer, March, 267–272
More on movies (ltr to ed). JK Loutzenhiser, Oct, 1159–1160
1977 anniversaries. G Mora, Dec, 1400–1404
The psychiatrist: in the mainstream or on the banks of medicine? TP Hackett, April, 432–434
A representative psychiatrist: the career and contributions of Sir Aubrey Lewis. M Shepherd, Jan, 7–13
Revolutions and the rights of man. GM Carstairs, Sept, 979–983
Social discrediting of psychiatry: the protasis of legal disfranchisement. PE Dietz, Dec, 1356–1360
Ten years of change in alcoholism treatment and delivery systems. EM Pattison, March, 261–266
Ten years of inpatient programs for alcoholic patients. RA Moore, May, 542–545

HORMONES

The effect of alcohol and smoking on testosterone function and aggression in chronic alcoholics. H Persky, CP O'Brien, E Fine, WJ Howard, MA Khan, RW Beck, June, 621–625
An evaluation of a unique new antipsychotic agent, sulpiride: effects on serum prolactin and growth hormone levels. DH Mielke, DM Gallant, C Kessler, Dec, 1371–1375
Hormones and sexual orientation in men. RC Friedman, I Dyrenfurth, D Linkie, R Tendler, JL Fleiss, May, 571–572
Melatonin, MSH, and psychosis (ltr to ed). M Baron, and reply of JS Carman, RM Post, FK Goodwin, R Buswell, May, 583–584
Pituitary thyrotropin response to thyrotropin-releasing hormone in affective illness: relationship to spinal fluid amine metabolites. PW Gold, FK Goodwin, T Wehr, R Rebar, Sept, 1028–1031
Plasma testosterone in homosexual and heterosexual women. NK Gartrell, DL Loriaux, TN Chase, Oct, 1117–1119
Psychoneuroendocrinology of affective disorder: an overview. PG Ettigi, GM Brown, May, 493–501
Testosterone and components of aggressive and sexual behavior in man. PM Monti, WA Brown, DP Corriveau, June, 692–694
Thyroid function and growth hormone secretion in amitriptyline-treated depression. SB Leichter, L Kirstein, ND Martin, Nov, 1270–1272

HOSPITALS AND HOSPITALIZATION

Asylums revisited. R Peele, PV Luisada, MJ Lucas, D Rudisell, D Taylor, Oct, 1077–1081
Brief hospitalization: a two-year follow-up. MI Herz, J Endicott, RL Spitzer, May, 502–507
Children's rights on entering therapeutic institutions. D Miller, RA Burt, Feb, 153–156
Creative "restraints" (ltr to ed). MS Weiner, July, 821
On denying the incredible: unexplained deaths in a VA hospital. P Kroll, KR Silk, KR Chamberlain, RJ Ging, Dec, 1376–1380
Effects of payment mode on clinic attendance and rehospitalization. KL Davis, FM Estess, SC Simonton, RA Gonda, May, 576–578
Homicide and deinstitutionalization of the mentally ill. F Grunberg, BI Klinger, B Grumet, June, 685–687
Patient responsibility and the AMA discharge—a one-year follow-up study, DJ Withersty, Dec, 1442–1444
Planning for a mental hospital phasedown. MP Lawton, MB Lipton, MC Fulcomer, MH Kleban, Dec, 1386–1390
Retrospective audit: depressive neurosis. SD Morrison, March, 299–301
The state hospital: facility of last resort. HR Lamb, Oct, 1151–1152
Ten years of inpatient programs for alcoholic patients. RA Moore, May, 542–545

HOSTILITY AND AGGRESSION

Anger arousal by a motion picture: a methodological note. WA Brown, DP Corriveau, PM Monti, Aug, 930–931
Anger and fear. HB Danesh, Oct, 1109–1112
Borderline rage and the therapist's response. T Nadelson, July, 748–751
The effect of alcohol and smoking on testosterone function and aggression in chronic alcoholics. H Persky, CP O'Brien, E Fine, WJ Howard, MA Khan, RW Beck, June, 621–625
Episodic dyscontrol and family dynamics. HT Harbin, Oct, 1113–1116
Impact of dramatized television entertainment on adult males. R Gorney, D Loye, G Steele, Feb, 170–174
Lithium in the treatment of a child abuser. BM Panter, Dec, 1436–1437
Rape: power, anger, and sexuality. AN Groth, AW Burgess, LL Holmstrom, Nov, 1239–1243
Testosterone and components of aggressive and sexual behavior in man. PW Monti, WA Brown, DP Corriveau, June, 692–694
Voluntary and involuntary treatment of aggressive patients. BJ Madden, May, 553–555

HYPERACTIVITY

Adult brain dysfunction (ltr to ed). DL Hurst, May, 587
Auditory evoked potentials and selective attention in formerly hyperactive adolescent boys. AJ Zambelli, JS Stamm, S Maitinsky, DL Loiselle, July, 742–747
The effects of caffeine on reaction time in hyperkinetic and normal children. CC Reichard, ST Elder, Feb, 144–148
Hyperactivity or affective illness? (ltr to ed). ND Bowdan, March, 329
Psychopathology and mental retardation: a statistical study of 100 mentally retarded children treated at a psychiatric clinic: II. Hyperactivity. I Philips, N Williams, April, 418–419
Urinary catecholamine metabolites in hyperkinetic boys treated with *d*-amphetamine. WO Shekim, H Dekirmenjian, JL Chapel, Nov, 1276–1279

HYSTERIA

Briquet's syndrome, hysterical personality, and the MMPI. BI Liskow, P Clayton, R Woodruff, S Guze, R Cloninger, Oct, 1137–1139
Lateralization of conversion symptoms: more frequent on the left. D Galin, R Diamond, D Braff, May, 578–580
Paroxysmal kinesigenic choreoathetosis or hysteria? DA Waller, Dec, 1439–1440

INSURANCE

Cost, utilization, and utilization review of mental health services in a prepaid group practice plan. SS Goldensohn, Nov, 1222–1226
The effects of national health insurance on Canadian psychiatry: the Ontario experience. B Liptzin, March, 248–252
Problems in analyzing the comparative costs of private versus public psychiatric care. SS Sharfstein, CA Taube, ID Goldberg, Jan, 29–32
Psychiatric peer review: the Washington, D.C., experience, 1972–1975. P Chodoff, P Santora, Feb, 121–125

INTERDISCIPLINARY RELATIONS

Challenging the medical student in a psychiatry clerkship. LS Linet, Jan, 53–55

Methadone maintenance in a patient on chronic hemodialysis. WM Glazer, GL Cohn, Aug, 931–932

ISOLATION

The psychological effects of isolation in protected environments. J Kellerman, D Rigler, SE Siegel, May, 563–565

LANGUAGE AND LANGUAGE DISTURBANCES

Anticholinergic psychosis in a bilingual: a case study. E Laski, E Taleporos, Sept, 1038–1040

LAW SUITS

Criminal law: implications for psychiatry? (ltr to ed). HL Hartman, Oct, 1162
Federal constraints: earned or unearned? DT Chalkley, Aug, 911–913
The Hearst trial and the confidentiality of residency records. LC Terr, Nov, 1238–1286
Recent mental health litigation: a critical perspective. AA Stone, March, 273–279
Social discrediting of psychiatry: the protasis of legal disfranchisement. PE Dietz, Dec, 1356–1360
Tarasoff: protective privilege versus public peril. H Gurevitz, March, 289–292

LIFE CYCLE

The life cycle and psychiatric education (ltr to ed). RN Butler, and reply of JS Eaton Jr, Oct, 1157–1158
Life planning: an educational approach to change. HJ Lurie, Aug, 878–882

LIFESTYLES

Life planning: an educational approach to change. HJ Lurie, Aug, 878–882
Some effects of the new feminism. R Moulton, Jan, 1–6
The successful professional woman: on being married to one. T Nadelson, L Eisenberg, Oct, 1071–1076

LITERATURE, PSYCHIATRIC

Asylums revisited. R Peele, PV Luisada, MJ Lucas, D Rudisell, D Taylor, Oct, 1077–1081
A computer-based lithium library (ltr to ed). JW Jefferson, JH Greist, Sept, 1049

MARRIAGE AND MARITAL THERAPY

Costs of the new feminism (ltr to ed). PK Pati, June, 704
The successful professional woman: on being married to one. T Nadelson, L Eisenberg, Oct, 1071–1076

MEDIA

Anger arousal by a motion picture: a methodological note. WA Brown, DP Corriveau, PM Monti, Aug, 930–931
Fact and fiction (ltr to ed). J Rubin, and reply of I Schneider, Dec, 1452
Guidelines for psychiatrists working with the communications media (off acts). May, 609–611
Images of the mind: psychiatry and the commercial film. I Schneider, June, 613–620
Impact of dramatized television entertainment on adult males. R Gorney, D Loye, G Steele, Feb, 170–174
More on movies (ltr to ed). JK Loutzenhiser, Oct, 1159–1160
An unfair portrayal of psychiatry (ltr to ed). EM Torch, Sept, 1044

MEDITATION

Another approach to self-induced depersonalization (ltr to ed). MA Simpson, and reply of RB Kennedy, Dec, 1449–1450
Position statement on meditation (off acts). June, 720
Transcendental meditation as an alternative to heroin abuse in servicemen. DJ Anderson, Nov, 1308–1309

MEMORY

ECT and memory loss. LR Squire, Sept, 997–1001
Memory loss with lithium? (ltr to ed). GF Bajor, May, 588
Memory loss with lithium treatment (ltr to ed). D Preodor, GY Wolpert, D Ostrow, P Holinger, EA Wolpert, Sept, 1047–1048
Myths of "shock therapy." M Fink, Sept, 991–996
Shock treatment, brain damage, and memory loss: a neurological perspective. J Friedberg, Sept, 1010–1014

MEN

Costs of the new feminism (ltr to ed). PK Pati, June, 704
Distinctions between male and female invested partners in sexual disorders. LR Derogatis, JK Meyer, BW Gallant, April, 385–390
Fatherhood and emotional illness. JO Cavenar Jr, NT Butts, April, 429–431
Hormones and sexual orientation in men. RC Friedman, I Dyrenfurth, D Linkie, R Tendler, JL Fleiss, May, 571–572
Impact of dramatized television entertainment on adult males. R Gorney, D Loye, G Steele, Feb, 170–174
Impotence responsive to glyceryl trinitrate. JW Mudd, Aug, 922–925; correction, Nov, 1315
Paranoid schizophrenia in a 47,XYY male. E Dorus, W Dorus, MA Telfer, June, 687–689
Testosterone and components of aggressive and sexual behavior in man. PM Monti, WA Brown, DP Corriveau, June, 692–694

MENTAL HEALTH, CURRENT ISSUES

Accountability, public policy, and psychiatry. AR Somers, Sept, 959–965
Current perspectives on ECT: a discussion. FH Frankel, Sept, 1014–1019
In defense of community mental health. J Zusman, HR Lamb, Aug, 887–890
ECT and ethical psychiatry. C Salzman, Sept, 1006–1009
The medical basis of psychiatry. AM Ludwig, E Othmer, Oct, 1087–1092
Myths of "shock therapy." M Fink, Sept, 991–996
Presidential address: a profession worthy of the public trust. RW Gibson, July, 723–728

Psychiatric eclecticism: a cognitive view. J Yager, July, 736–741
Psychiatrists in CMHCs (ltr to ed). FP Kosbab, and reply of JS Eaton Jr, LS Goldstein, Dec, 1450–1451
Psychiatry in crisis. JS Eaton Jr, LS Goldstein, June, 642–645
Psychiatry, the healthy invalid. JD Frank, Dec, 1349–1355
Psychotherapy and pharmacotherapy: conceptual issues. JP Docherty, SR Marder, DP van Kammen, SG Siris, May, 529–533
Regulating psychiatric practice. PR Fleischman, March, 296–298
Research barriers in psychopharmacology. JO Cole, Aug, 896–898
Response to the presidential address. J Weinberg, July, 729–730
Revolutions and the rights of man. GM Carstairs, Sept, 979–983
Subjects' rights, freedom of inquiry, and the future of research in the addictions. RE Meyer, Aug, 899–903
An unfair portrayal of psychiatry (ltr to ed). EM Torch, Sept, 1044

MENTAL ILLNESS, GENERAL

Atrial myxoma masquerade. RN Wharton, Dec, 1441–1442
Boarding schools: effects on the mental health of Eskimo adolescents. J Kleinfeld, J Bloom, April, 411–417
On cancer and the emotions (ltr to ed). RS Brown, and reply of FG Surawicz, May, 585
Chromosome variants in children with psychiatric disorders. B Say, NJ Carpenter, PR Lanier, C Banez, K Jones, JG Coldwell, April, 424–426
Community psychiatry in Tutuila, American Samoa. WE Walters, Aug, 917–919
Criminality and mental illness: a study of arrest rates in a rural state. JR Durbin, RA Pasewark, D Albers, Jan, 80–83
The crisis in mental health research. BS Brown, Feb, 113–120
Diagnosis: schizophrenia versus posterior aphasia. SN Gerson, DF Benson, SH Frazier, Sept, 966–969
Fatherhood and emotional illness. JO Cavenar Jr, NT Butts, April, 429–431
Fear of the mentally ill: empirical support for the common man's response. JM Lagos, K Perlmutter, H Saexinger, Oct, 1134–1137
Forensic psychiatry: female offenders. M Herjanic, FA Henn, RH Vanderpearl, May, 556–558
Homicide and deinstitutionalization of the mentally ill. F Grunberg, BI Klinger, B Grumet, June, 685–687
Mental health in jail (ltr to ed). EF Kal, April, 463
Platelet MAO activity in schizophrenia and other psychiatric illnesses. J Sullivan, CN Stanfield, C Dackis, Oct, 1098–1103
Position statement on the right to adequate care and treatment for the mentally ill and mentally retarded (off acts). March, 354–355
Prognostic implications of various drinking patterns in psychiatric patients. BA Ritzler, JS Strauss, A VanOrd, RF Kokes, May, 546–549
Psychiatric disturbances associated with Erhard Seminars Training: I. A report of cases. LL Glass, MA Kirsch, FN Parris, March, 245–247
Psychiatric disturbances associated with Erhard Seminars Training: II. Additional cases and theoretical considerations. MA Kirsch, LL Glass, Nov, 1254–1258
Psychiatric illness in relatives of patients with Parkinson's disease: a preliminary report. SL Stern, HI Hurtig, J Mendels, D Balaban, April, 443–444
The psychological effects of isolation in protected environments. J Kellerman, D Rigler, SE Siegel, May, 563–565
Social disability in chronic psychiatric patients. JA Sylph, HE Ross, HB Redward, Dec, 1391–1394
A study of 100 physician psychiatric inpatients. RE Jones, Oct, 1119–1123
Temporal disorganization and inner-outer confusion in acute mental illness. FT Melges, AM Freeman III, Aug, 874–877

MENTAL RETARDATION

Erotomanic delusions in a mentally retarded patient. B Greyson, S Akhtar, March, 325–326
Psychopathology and mental retardation: a statistical study of 100 mentally retarded children treated at a psychiatric clinic: II. Hyperactivity. I Philips, N Williams, April, 418–419

MILITARY PSYCHIATRY

Depression in veterans two years after Viet Nam. EP Nace, AL Meyers, CP O'Brien, N Ream, J Mintz, Feb, 167–170
Politics or science? (ltr to ed). SL Oken, and reply of TC Bond, Aug, 936–937
Transcendental meditation as an alternative to heroin abuse in servicemen. DJ Anderson, Nov, 1308–1309

MINORITY GROUPS

Boarding schools: effects on the mental health of Eskimo adolescents. J Kleinfeld, J Bloom, April, 411–417
Inhalant abuse in an Indian boarding school. MF Schottstaedt, JW Bjork, Nov, 1290–1293
Voodoo in Africa and the United States. KM Golden, Dec, 1425–1427

MORAL THERAPY

Moral therapy and the problem of morale. L Sederer, March, 267–272

MUNCHAUSEN SYNDROME

Request for information (ltr to ed). SE Hyler, Feb, 213

MUSICOLOGY, PSYCHIATRIC

Tempo errors and mania. J Stein, April, 454–456

NATIONAL INSTITUTE OF MENTAL HEALTH

The crisis in mental health research. BS Brown, Feb, 113–120
The educational challenge of consultation-liaison psychiatry. JS Eaton Jr, R Goldberg, E Rosinski, WS Allerton, March Supp, 20–23
The function and organization of NIMH (ltr to ed). CL Bowden, Aug, 939–940
Governmental peer review of training programs in child psychiatry. LB Silver, R Brunstetter, D Renshaw, JP Comer, March Supp, 11–14
Introduction. BS Brown, March Supp, 1
Postscript. FN Waldrop, March Supp, 29
Psychiatric education: state of the art, 1976. JS Eaton Jr, RS Daniels, H Pardes, March Supp, 2–6

NEUROPSYCHIATRY

Auditory evoked potentials and selective attention in formerly hyperactive adolescent boys. AJ Zambelli, JS Stamm, S Maitinsky, DL Loiselle, July, 742–747
The brain as a dream state generator: an activation-synthesis hypothesis of the dream process. JA Hobson, RW McCarley, Dec, 1335–1348
Brain mechanisms associated with therapeutic actions of benzodiazepines: focus on neurotransmitters. SH Snyder, SJ Enna, AB Young, June, 662–665

Electrophysiological (H-reflex) studies of patients with tardive dyskinesia. JW Crayton, RC Smith, D Klass, S Chang, SE Ericksen, July, 775–781
Increased sympathetic nervous system activity in alcoholic patients treated with disulfiram. CR Lake, LF Major, MG Ziegler, IJ Kopin, Dec, 1411–1413
Lateralization of conversion symptoms: more frequent on the left. D Galin, R Diamond, D Braff, May, 578–580
Methodology in a case report (ltr to ed). RA Kuwik, and reply of G Asnis, Oct, 1158
The neurobiological origins of psychoanalytic dream theory. RW McCarley, JA Hobson, Nov, 1211–1221
Parkinson's disease, depression, and ECT: a review and case study. G Asnis, Feb, 191–195
Paroxysmal kinesigenic choreoathetosis or hysteria? DA Waller, Dec, 1439–1440
Shock treatment, brain damage, and memory loss: a neurological perspective. J Friedberg, Sept, 1010–1014
Should skull films be routine? (ltr to ed). RT Rubin, Feb, 211–212
Urinary catecholamine metabolites in hyperkinetic boys treated with *d*-amphetamine. WO Shekim, H Dekirmenjian, JL Chapel, Nov, 1276–1279

NEUROSIS

Ictal and subictal neurosis (ltr to ed). AD Jonas, and reply of DO Lewis, Sept, 1051–1052
L-Tryptophan in obsessive-compulsive disorders. JA Yaryura-Tobias, HN Bhagavan, Nov, 1298–1299

NOMENCLATURE, PSYCHIATRIC

Briquet's syndrome, hysterical personality, and the MMPI. BI Liskow, P Clayton, R Woodruff, S Guze, R Cloninger, Oct, 1137–1139
Cyclothymic disorder: validating criteria for inclusion in the bipolar affective group. HS Akiskal, AH Djenderedjian, RH Rosenthal, MK Khani, Nov, 1227–1233
On diagnostic classification (ltr to ed). AF Kinzel, and reply of R Abrams, MA Taylor, July, 823
Dispensing with "psychosomatic" (ltr to ed). M Shepherd, and reply of ZJ Lipowski, Oct, 1158–1159
Dysmorphophobia: symptom or disease? NC Andreasen, J Bardach, June, 673–676
Exhibitionism or narcissism? (ltr to ed). M Eber, and reply of MH Hollender, CW Brown, HB Roback, Sept, 1053
More on "psychosomatics" (ltr to ed). M Shepherd, Dec, 1452

OBESITY

A misinterpretation? (ltr to ed). RS Kalucy, TRE Pilkington, AH Crisp, and reply of MJ Mills, AJ Stunkard, April, 459–460
Phenytoin treatment of the binge-eating syndrome. BM Wermuth, KL Davis, LE Hollister, AJ Stunkard, Nov, 1249–1253
Weight reduction in schizophrenics by molindone. G Gardos, JO Cole, March, 302–304

OBITUARIES

David M. Levy, 1892–1977 (in mem). W Goldfarb, Aug, 934

ORGAN TRANSPLANT

Kidney donors revisited. JR Marshall, CH Fellner, May, 575–576

ORGANIC BRAIN SYNDROME

Danger of overreliance on computerized cranial tomography. CE Wells, GW Duncan, July, 811–813
Lithium treatment of patients with affective illness associated with organic brain symptoms. LD Young, I Taylor, V Holmstrom, Dec, 1405–1407

OUTPATIENT TREATMENT

Effects of payment mode on clinic attendance and rehospitalization. KL Davis, FM Estess, SC Simonton, RA Gonda, May, 576–578
Outpatient treatment of schizophrenia. N Hansell, GL Willis, Oct, 1082–1086
Planning for a mental hospital phasedown. MP Lawton, MB Lipton, MC Fulcomer, MH Kleban, Dec, 1386–1390
A survey of tardive dyskinesia in psychiatric outpatients. GM Asnis, MA Leopold, RC Duvoisin, A Schwartz, Dec, 1367–1370

OVERVIEW ARTICLES

Psychoneuroendocrinology of affective disorder: an overview. PG Ettigi, GM Brown, May, 493–501
Psychosomatic medicine in the seventies: an overview. ZJ Lipowski, March, 233–244
Psychotherapies: an overview. TB Karasu, Aug, 851–863

PAIN

On atypical facial pain (ltrs to ed). JJ Pinsky; BL Crue; JD Pro, CE Wells; S Lesse; V Hyrman, April, 458–459
Atypical facial pain and hypomania (ltr to ed). JW Jefferson, March, 330
More on atypical facial pain (ltr to ed). M Fishman, July, 821

PATIENT RIGHTS

Changing law and clinical dilemmas. WD Weitzel, March, 293–295
Collaboration between Ohio psychiatrists and the legislature to update commitment laws. VM Victoroff, July, 752–755
Criminal law: implications for psychiatry? (ltr to ed). HL Hartman, Oct, 1162
ECT and ethical psychiatry. C Salzman, Sept, 1006–1009
Ethics in alcoholism research (ltr to ed). M Goldberg, and reply of H Persky, CP O'Brien, E Fine, Dec, 1447
On existence of dangerousness (ltr to ed). LR Doss, and reply of VR Adebimpe, July, 817–818
Federal constraints: earned or unearned? DT Chalkley, Aug, 911–913
Freedom of inquiry and subjects' rights: historical perspective. D Musto, Aug, 893–896
Freedom of inquiry and subjects' rights: an introduction. D Reiss, Aug, 891–892
The functions of human subjects review committees. BH Gray, Aug, 907–910
Informed consent and confidentiality: proposed new approaches in Illinois. R Schlensky, Dec, 1416–1418
John Stuart Mill on the liberty of the mentally ill: a historical note. J Monahan, Dec, 1428–1429
Patient responsibility and the AMA discharge—a one-year follow-up study. DJ Withersty, Dec, 1442–1444
Problems in follow-up studies. LN Robins, Aug, 904–907
Recent mental health litigation: a critical perspective. AA Stone, March, 273–279
Research barriers in psychopharmacology. JO Cole, Aug, 896–898

Subjects' rights, freedom of inquiry, and the future of research in the addictions. R Meyer, Aug, 899–903
Tests of competency to consent to treatment. LH Roth, A Meisel, CW Lidz, March, 279–284
Toward a model of the legal doctrine of informed consent. A Meisel, LH Roth, CW Lidz, March, 285–289

PATIENT-THERAPIST RELATIONSHIP

Borderline rage and the therapist's response. T Nadelson, July, 748–751
Cognitive and interactive aspects of splitting. MJ Horowitz, May, 549–553
Contractual agreements with adolescents? (ltr to ed). S Smith, and reply of D Miller, Oct, 1160–1161
Dangerousness, confidentiality, and the duty to warn. LH Roth, A Meisel, May, 508–511
The ethics of practice in adolescent psychiatry. D Miller, April, 420–424
Patients' attitudes toward behavior therapy and psychotherapy. RB Sloane, FR Staples, K Whipple, AH Cristol, Feb, 134–137
A "professional will" (ltr to ed). EL Lipton, May, 585
Psychotherapies: an overview. TB Karasu, Aug, 851–863
Psychotherapy and pharmacotherapy: conceptual issues. JP Docherty, SR Marder, DP van Kammen, SG Siris, May, 529–533
The therapist as participant-observer (ltr to ed). TS Holmes, Nov, 1313
Voluntary and involuntary treatment of aggressive patients. DJ Madden, May, 553-555

PEER REVIEW

An examination of the federal psychiatric training grant peer review process. CB Wilkinson, VI Reus, June, 637–641
Peer review and professional ethics. F Sullivan, Feb, 186–188
Psychiatric peer review: the Washington, D.C., experience, 1972–1975. P Chodoff, P Santora, Feb, 121–125
Retrospective audit: depressive neurosis. SD Morrison, March, 299–301

PERSONALITY DISORDER

Cyclothymic disorder: validating criteria for inclusion in the bipolar affective group. HS Akiskal, AH Djenderedjian, RH Rosenthal, MK Khani, Nov, 1227–1233

PHYSICAL ILLNESS AND IMPAIRMENT

Atrial myxoma masquerade. RN Wharton, Dec, 1441–1442
On cancer and the emotions (ltr to ed). RS Brown, and reply of FG Surawicz, May, 585
Clinical picture of atypical anorexia nervosa associated with hypothalamic tumor. JH White, P Kelly, K Dorman, March, 323–325
Coexisting childhood schizophrenia and myasthenia gravis treated successfully with neostigmine bromide. RC Schnackenberg, G Holmes, Sept, 1025–1027
Coincidental improvement in asthma during lithium treatment. SJ Nasr, RW Atkins, Sept, 1042–1043
Diagnosis: schizophrenia versus posterior aphasia. SN Gerson, DF Benson, SH Frazier, Sept, 966–969
Ganser-like signs in carbon monoxide encephalopathy (ltr to ed). J McEvoy, T Campbell, Dec, 1448–1449
Group therapy with the terminally ill. ID Yalom, C Greaves, April, 396–400
Impotence responsive to glyceryl trinitrate. JW Mudd, Aug, 922–925; correction, Nov, 1315
Kidney donors revisited. JR Marshall, CH Fellner, May, 575–576
Medical histories of delinquent and nondelinquent children: an epidemiological study. DO Lewis, SS Shanok, Sept, 1020–1025; correction, Dec, 1452–1453
Methadone maintenance in a patient on chronic hemodialysis. WM Glazer, GL Cohn, Aug, 931–932
Patient progress rounds on a university hospital cardiology service. C Hollingsworth, R Hoffman, C Scalzi, B Sokol, Jan, 42–44
Pediatric bone marrow transplantation: psychosocial aspects. B Pfefferbaum, MM Lindamood, FM Wiley, Nov, 1299–1301
Primary and secondary benefits from treatment for alcoholism. E Edwards, S Bucky, P Coben, S Fichman, NH Berry, June, 682–683
Psychiatric illness in relatives of patients with Parkinson's disease: a preliminary report. SL Stern, HI Hurtig, J Mendels, D Balaban, April, 443–444
The psychological effects of isolation in protected environments. J Kellerman, D Rigler, SE Siegel, May, 563–565
Rapid treatment of delirium in critically ill patients. DP Moore, Dec, 1431–1432
The role of benzodiazepines in nonpsychiatric medical practice. L Lasagna, June, 656–658
Secondary mania? a case report. KN Wiesert, HC Hendrie, Aug, 929–930
Spinal cord injury: a role for the psychiatrist. TD Stewart, May, 538–541
Treatment of depression in the medically ill geriatric patient: a case report. CG Dunn, D Gross, April, 448–450

PHYSICIANS

Dehumanization in medical education (ltr to ed). EM Stein, and reply of PJ Fink, Aug, 937–938
Focused psychiatric curriculum selection: student, psychiatrist, and nonpsychiatrist physician expectations. W Johnson, J Snibbe, K Hoffman, L Evans, Oct, 1126–1130
A study of 100 physician psychiatric inpatients. RE Jones, Oct, 1119–1123

PLACEBOS

A note on the addictive personality: addiction to placebos. I Mintz, March, 327
On placebo effects (ltr to ed). BE Green, and reply of MH Sheard, JL Marini, Aug, 935–936

POLICE

Suicide among police. MF Heiman, Nov, 1286–1290

POLITICS

Freedom of inquiry and subjects' rights: an introduction. D Reiss, Aug, 891–892
The functions of human subjects review committees. BH Gray, Aug, 907–910
Patterns of Association voting behavior: I. Demographic correlates of voting/nonvoting and preference for candidates/issues. L Gurel, TW Lorei, CW Nelson, MJ Myers, Jan, 33–37
Politics or science? (ltr to ed). SL Oken, and reply of TC Bond, Aug, 936–937
Psychiatric observations of state and local politicians. E Messner, Oct, 1140–1142

POSITION STATEMENTS

Position statement on meditation (off acts). June, 720
Position statement on the problem-oriented record-keeping system (off acts). March, 356
Position statement on the right to adequate care and treatment for the mentally ill and mentally retarded (off acts). March, 354–355
Position statement on support for psychiatric research (off acts). May, 612

PREDICTION OF OUTCOME, PROGNOSIS

Catatonia: prediction of response to somatic treatments. R Abrams, MA Taylor, Jan, 78–80
A comparison of outcome in adolescent- and late-onset bipolar manic-depressive illness. GA Carlson, K Jamison, YB Davenport, Aug, 919–922
Methodology in REM sleep studies (ltr to ed). I Maany, and reply of R Greenberg, C Pearlman, Aug, 939
Prognostic implications of various drinking patterns in psychiatric patients. BA Ritzler, JS Strauss, A VanOrd, RF Kokes, May, 546–549

PREGNANCY

Fatherhood and emotional illness. JO Cavenar Jr, NT Butts, April, 429–431
Fluphenazine decanoate during pregnancy. MF Cleary, July, 815–816
Newborn dopamine-β-hydroxylase, minor physical anomalies, and infant temperament. JL Rapoport, C Pandoni, M Renfield, CR Lake, MG Ziegler, June, 676–679

PREVENTION

The prevention of tardive dyskinesia. GE Crane, July, 756–758

PRISON AND PRISONERS

Mental health in jail (ltr to ed). EF Kal, April, 463

PROTECTED ENVIRONMENTS

The psychological effects of isolation in protected environments. J Kellerman, D Rigler, SE Siegel, May, 563–565

PSYCHIATRISTS

The emotionally disturbed psychiatric resident. AT Russell, RO Pasnau, ZC Taintor, Jan, 59–62
Focused psychiatric curriculum selection: student, psychiatrist, and nonpsychiatrist physician expectations. W Johnson, J Snibbe, K Hoffman, L Evans, Oct, 1126–1130
Illustrious psychiatric administrators. M Greenblatt, SO Rose, June, 626–630
A "professional will" (ltr to ed). EL Lipton, May, 585
A representative psychiatrist: the career and contributions of Sir Aubrey Lewis. M Shepherd, Jan, 7–13
On residency: emotions and spouses' involvement (ltr to ed). JC Goetzl, U Goetzl; DP Miley, BJ Conn, and reply of AT Russell, Oct, 1155–1156

PSYCHIATRY, CRITICISM OF

The psychiatrist: in the mainstream or on the banks of medicine? TP Hackett, April, 432–434
Psychiatry, the healthy invalid. JD Frank, Dec, 1349–1355
Research barriers in psychopharmacology. JO Cole, Aug, 896–898
Social discrediting of psychiatry: the protasis of legal disfranchisement. PE Dietz, Dec, 1356–1360
Subjects' rights, freedom of inquiry, and the future of research in the addictions. RE Meyer, Aug, 899–903
An unfair portrayal of psychiatry (ltr to ed). EM Torch, Sept, 1044

PSYCHIATRY, DEFINITION AND ROLE

Accountability, public policy, and psychiatry. AR Somers, Sept, 959–965
Consultation in the college setting. EA Reid, May, 568–570
Consultation: what settings? (ltr to ed). AR Favazza, and reply of ZJ Lipowski, Oct, 1161–1162
The crisis in mental health research. BS Brown, Feb, 113–120
The function and organization of NIMH (ltr to ed). CL Bowden, Aug, 939–940
Images of the mind: psychiatry and the commercial film. I Schneider, June, 613–620
The medical basis of psychiatry. AM Ludwig, E Othmer, Oct, 1087–1092
The medical setting: is it beyond the psychiatrist? JJ Strain, March, 253–256
Moral therapy and the problem of morale. L Sederer, March, 267–272
More on movies (ltr to ed). JK Loutzenhiser, Oct, 1159–1160
Position statement on support for psychiatric research (off acts). May, 612
Presidential address: a profession worthy of the public trust. RW Gibson, July, 723–728
Psychiatric consultation: concepts and controversies. ZJ Lipowski, May, 523–528
Psychiatric eclecticism: a cognitive view. J Yager, July, 736–741
The psychiatrist: in the mainstream or on the banks of medicine? TP Hackett, April, 432–434
Psychiatrists in CMHCs (ltr to ed). FP Kosbab, Dec, 1450–1451
Psychiatry in crisis. JS Eaton Jr, LS Goldstein, June, 642–645
Psychiatry, the healthy invalid. JD Frank, Dec, 1349–1355
Regulating psychiatric practice. PR Fleischman, March, 296–298
The relationship of psychiatry to primary care. PJ Fink, Feb, 126–129
Response to the presidential address. J Weinberg, July, 729–730
Revolutions and the rights of man. GM Carstairs, Sept, 979–983
Social discrediting of psychiatry: the protasis of legal disfranchisement. PE Dietz, Dec, 1356–1360
Spinal cord injury: a role for the psychiatrist. TD Stewart, May, 538–541
The therapist as participant-observer (ltr to ed). TS Holmes, Nov, 1313

PSYCHOANALYSIS

The neurobiological origins of psychoanalytic dream theory. RW McCarley, JA Hobson, Nov, 1211–1221
Sexual dysfunctions and psychoanalysis. EM Levine, N Ross, June, 646–651
The treatment of drug abuse: evolution of a perspective. L Brill, Feb, 157–160

PSYCHOSIS

On atypical facial pain (ltrs to ed). JJ Pinsky; BL Crue; JD Pro, CE Wells; S Lesse, V Hyrman, April, 458–459

A case of lycanthropy. HA Rosenstock, KR Vincent, Oct, 1147–1149
Depersonalization and temporal disintegration in acute mental illness. AM Freeman III, FT Melges, June, 679–681
Diazepam withdrawal psychosis: a case report. MW Dysken, CH Chan, May, 573
Is panic normal? (ltr to ed). IJ Farber, and reply of JF Heiser, D DeFrancisco, May, 588
Low levels of dopamine β-hydroxylase and psychosis. JA Ewing, RA Mueller, BA Rouse, D Silver, Aug, 927–928
Melatonin, MSH, and psychosis (ltr to ed). M Baron, and reply of JS Carman, RM Post, FK Goodwin, R Buswell, May, 583–584
A methodological critique (ltr to ed). R Haier, and reply of NC Andreasen, Jan, 97–98
More on atypical facial pain (ltr to ed). M Fishman, July, 821
A positive response to rapid treatment (ltr to ed). NR Cutler, DJ Anderson, March, 329
Postpsychotic depression and the need for personal significance. BL MacKinnon, April, 427–429
Psychotherapy of severe depression. S Arieti, Aug, 864–868
Questions about rapid treatment (ltr to ed). WT Carpenter Jr, and reply of WH Anderson, JC Kuehnle, May, 584–585

PSYCHOSOMATIC MEDICINE

On atypical facial pain (ltrs to ed). JJ Pinsky; BL Crue; JD Pro, CE Wells; S Lesse; V Hyrman, April, 458–459
Atypical facial pain and hypomania (ltr to ed). JW Jefferson, March, 330
Dispensing with "psychosomatic" (ltr to ed). M Shepherd, and reply of ZJ Lipowski, Oct, 1158–1159
More on atypical facial pain (ltr to ed). M Fishman, July, 821
More on "psychosomatics" (ltr to ed). M Shepherd, Dec, 1452
Psychosomatic medicine in the seventies: an overview. ZJ Lipowski, March, 233–244
Rapidly recurring seizures of psychogenic origin. KP Poulose, AA Shaw, Oct, 1145–1146

PSYCHOSURGERY

Nuclear symptoms of schizophrenia after cingulotomy: a case report. JI Escobar, V Chandel, Nov, 1304–1306

PSYCHOTHERAPY

Cognitive and interactive aspects of splitting. MJ Horowitz, May, 549–553
Innovation or fad? (ltr to ed). AS Rogawski, and reply of FJ Braceland, Aug, 937
More on "free" psychotherapy (ltr to ed). SL Debow, and reply of J Paris, May, 588–589
Patients' attitudes toward behavior therapy and psychotherapy. RB Sloane, FR Staples, K Whipple, AH Cristol, Feb, 134–137
Premature interruption of psychotherapy: continuation of contact by telephone and correspondence. M Rosenbaum, Feb, 200–202
A primal primer for psychiatrists. D Rosen, April, 445–446
Psychotherapies: an overview. TB Karasu, Aug, 851–863
Psychotherapy and pharmacotherapy: conceptual issues. JP Docherty, SR Marder, DP van Kammen, SG Siris, May, 529–533
Psychotherapy of severe depression. S Arieti, Aug, 864–868
On teaching psychotherapy in a community mental health center. JD Nason, Dec, 1419–1421
Treating acute schizophrenia without drugs (ltr to ed). DP Moore; R Benson, and reply of WT Carpenter Jr, TH McGlashan, JS Strauss, June, 699–701
The treatment of acute schizophrenia without drugs: an investigation of some current assumptions. WT Carpenter Jr, TH McGlashan, JS Strauss, Jan, 14–20
Voluntary and involuntary treatment of aggressive patients. DJ Madden, May, 553–555

PUBLIC ACCOUNTABILITY

Accountability, public policy, and psychiatry. AR Somers, Sept, 959–965

RAPE

Rape: power, anger, and sexuality. AN Groth, AW Burgess, LL Holmstrom, Nov, 1239–1243

RECORDS

A computer-assisted, goal-oriented psychiatric progress note system. MJ Meldman, D Harris, RJ Pellicore, EL Johnson, Jan, 38–41
Confidentiality: a solution to the problem? (ltr to ed). FG Durgin, Aug, 939; correction, Oct, 1163
The Hearst trial and the confidentiality of residency records. LC Terr, Nov, 1283–1286
Position statement on the problem-oriented record-keeping system (off acts). March, 356
Problems in follow-up studies. LN Robbins, Aug, 904–907

REFUGEES

Placement and evaluation of Southeast Asian children (ltr to ed). BL Kennedy, BL Ersley, Aug, 938–939
Problems of Southeast Asian children in a refugee camp. RK Harding, JG Looney, April, 407–411

REHABILITATION

Primary and secondary benefits from treatment for alcoholism. D Edwards, S Bucky, P Coben, S Fichman, NH Berry, June, 682–683
Restructuring rehabilitation for women: programs for the female drug addict. KM Doyle, MA Quinones, G Tracy, D Young, J Hughes, Dec, 1395–1399

RELIGION AND MYSTICISM

Another approach to self-induced depersonalization (ltr to ed). MA Simpson, and reply of RB Kennedy, Dec, 1449–1450
Community psychiatry in Tutuila, American Samoa. WE Walters, Aug, 917–919
Request for information (ltr to ed). JR Lion, Feb, 213
Voodoo in Africa and the United States. KM Golden, Dec, 1425–1427

RESEARCH

The crisis in mental health research. BS Brown, Feb, 113–120
Ethics in alcoholism research (ltr to ed). M Goldberg, and reply of H Persky, CP O'Brien, E Fine, Dec, 1447
Federal constraints: earned or unearned? DT Chalkley, Aug, 911–913

Freedom of inquiry and subjects' rights: historical perspective. D Musto, Aug, 893–896
Freedom of inquiry and subjects' rights: an introduction. D Reiss, Aug, 891–892
The functions of human subjects review committees. BH Gray, Aug, 907–910
Position statement on support for psychiatric research (off acts). May, 612
Problems in follow-up studies. LN Robins, Aug, 904–907
Research barriers in psychopharmacology. JO Cole, Aug, 896–898
Research training in psychiatry. H Pardes, AM Freedman, V Reus, March Supp, 24–28
Subjects' rights, freedom of inquiry, and the future of research in the addictions. R Meyer, Aug, 899–903

RESEARCH DESIGN, STATISTICS

Anger arousal by a motion picture: a methodological note. WA Brown, DP Corriveau, PM Monti, Aug, 930–931
Clinical research techniques in tardive dyskinesia. WE Fann, JR Stafford, RL Malone, JD Frost, BW Richman, July, 759–762
Evaluating antianxiety agents in humans: experimental paradigms. EH Uhlenhuth, June, 659–662
Improvement or relief from side effects? (ltr to ed). JM Kane, and reply of WT Carpenter Jr, TH McGlashan, JS Strauss, July, 819–820
A methodological critique (ltr to ed). R Haier, and reply of NC Andreasen, Jan, 97–98
Methodology in a case report (ltr to ed). RA Kuwik, and reply of G Asnis, Oct, 1158
On placebo effects (ltr to ed). BE Green, and reply of MH Sheard, JL Marini, Aug, 935–936

SCHIZOPHRENIA

Diagnosis

Anhedonia and schizophrenia. M Harrow, RR Grinker, PS Holzman, L Kayton, July, 794–797
A case of lycanthropy. HA Rosenstock, KR Vincent, Oct, 1147–1149
Diagnosis: schizophrenia versus posterior aphasia. SN Gerson, DF Benson, SH Frazier, Sept, 966–969
On diagnostic classification (ltr to ed). AF Kinzel, and reply of R Abrams, MA Taylor, July, 823
Narcolepsy and schizophrenia (ltr to ed). KC Ullman, and reply of HI Spitz, B Shapiro, July, 822
Nuclear symptoms of schizophrenia after cingulotomy: a case report. JI Escobar, V Chandel, Nov, 1304–1306
Trends in the frequency of schizophrenia by different diagnostic approaches. J Kuriansky, BJ Gurland, RL Spitzer, J Endicott, June, 631–636

Research

γ-Aminobutyric acid (Gaba) and the dopamine hypothesis of schizophrenia. DP van Kammen, Feb, 138–143; correction, April, 463–464
Betel nut as a GABA blocker (ltr to ed). JR Smythies, July, 822
A bufotenin-like substance in the urine of schizophrenics. AC Cottrell, MF McLeod, WR McLeod, March, 322–323
Dopamine hypersensitivity and tardive dyskinesia (ltr to ed). RM Allen, and reply of GN Pandey, DL Garver, CA Tamminga, JM Davis, Oct, 1154–1155
GHB and GABA (ltr to ed). F Plantey, and reply of DP van Kammen, Sept, 1045–1046
In vitro half-life of ^{14}C-tryptamine in whole blood of drug-free chronic schizophrenic patients. EF Domino, S Gahagan, Nov, 1280–1282
More on genetic transmission in schizophrenia (ltr to ed). MA Taylor, R Abrams, and reply of SS Kety, April, 457–458
Paranoid schizophrenia in a 47,XYY male. E Dorus, W Dorus, MA Telfer, June, 687–689
Platelet MAO activity in schizophrenia and other psychiatric illnesses. J Sullivan, CN Stanfield, C Dackis, Oct, 1098–1103
Platelet monoamine oxidase activity in schizophrenic patients. RE Becker, EG Shaskan, May, 512–517

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

Warner/Chilcott Introduces

VERSTRAN®
(prazepam) C IV

A new addition for the treatment of anxiety

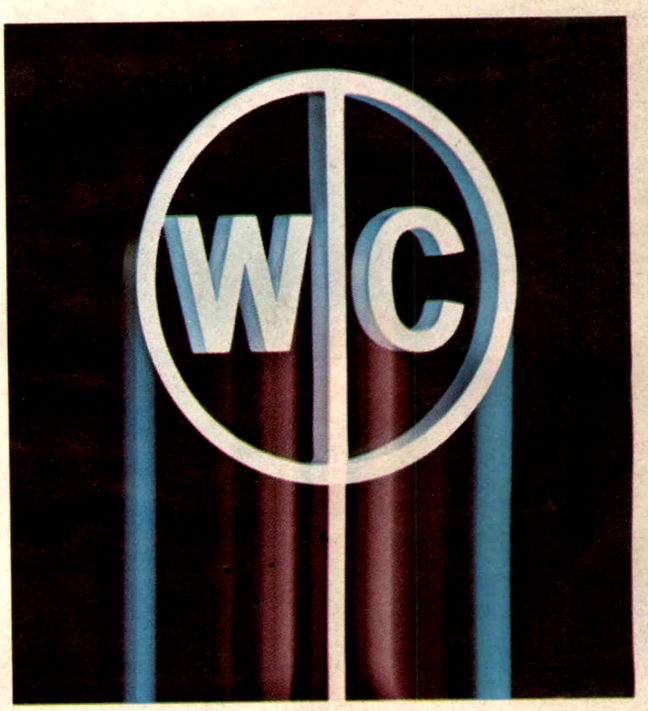
Verstran® (prazepam) provides the antianxiety effectiveness you expect from a benzodiazepine —plus dosage versatility

New Verstran
Reduces symptoms of anxiety–whether psychic or somatic in origin.

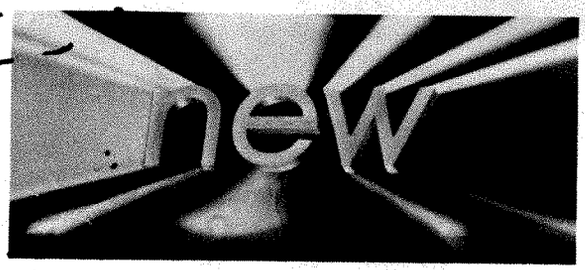
New Verstran
Provides the simplicity of a single scored 10 mg tablet to facilitate titration.

Plus 2 dosage options

Option 1:



New Verstran can be administered in a daily divided dose.
Starting with 10 mg b.i.d., dosage may be titrated gradually within a range of 20 to 60 mg per day in accordance with response.



Option 2:

New Verstran can be taken once a day at bedtime.
The usual starting dose for this regimen is 20 mg (two 10 mg tablets). Optimum dosage usually ranges from 20 to 40 mg daily.

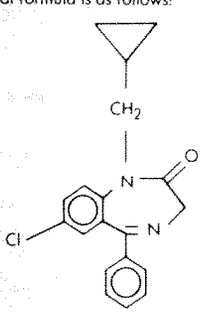
*Data on file, Warner/Chilcott Medical Department.
†Number of patients cited represents those evaluated at final observation.
Please see last page of this advertisement for full product information.

New Verstran
Eleven double-blind studies totaling 560 patients were conducted using b.i.d. and h.s. dosage regimens. Global Improvement Ratings, made at week 2, 3, or 4 for the b.i.d. dose, and at week 3 or 4 for the h.s. dose, confirmed the clinical efficacy of Verstran in both dosage options.*†

VERSTRAN®
(prazepam) Ⓒ IV

■ **New Verstran**
Effective for the symptomatic relief of a wide range of anxiety conditions—whether psychic or somatic in origin.

■ **New Verstran**
The simplicity of a single scored 10 mg tablet.



■ **New Verstran**
The versatility of fully effective divided daily or single nighttime dosage.

■ **New Verstran**
Side effects are characteristic of benzodiazepine drugs.*

Verstran* (prazepam) Ⓒ IV

Caution: Federal law prohibits dispensing without prescription.

Description: Verstran (prazepam); a benzodiazepine derivative, is identified chemically as 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1, 4-benzodiazepin-2-one. The molecular weight is 324.8 and the structural formula is as follows:

Clinical Pharmacology: Studies in normal subjects have shown that Verstran (prazepam) has depressant effects on the central nervous system. Oral administration of single doses as high as 60 mg and divided doses up to 100 mg t.i.d. (300 mg total daily dose) were without toxic effects.

Single oral doses of Verstran in normal subjects produced peak blood levels at 6 hours postadministration, with significant amounts still present after 48 hours. Verstran was slowly absorbed over a prolonged period, rather constant blood levels were maintained, and excretion was prolonged. The mean half-life of prazepam measured in subjects given 10 mg t.i.d. for one week was 63 (± 15 s.d.) hours before and 70 (± 10 s.d.) hours after multiple dosing—a nonsignificant difference. Human metabolism studies showed that prior to elimination from the body, prazepam is metabolized in large part to 3-hydroxyprazepam and oxazepam.

Indications: Verstran (prazepam) is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

Contraindications: Verstran (prazepam) is contraindicated in patients with a known sensitivity to the drug and in those with acute narrow angle glaucoma.

Warnings: Verstran (prazepam) is not recommended in psychotic states and in those psychiatric disorders in which anxiety is not a prominent feature.

Patients taking Verstran should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery, including motor vehicles.

Because Verstran has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, including phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants. The effects of alcohol may also be increased.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions:
Use in Pregnancy and Lactation:
An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Verstran (prazepam) a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug. In view of their molecular size, Verstran and its metabolites are probably excreted in human milk. Therefore, this drug should not be given to nursing mothers.

In those patients in whom a degree of depression accompanies the anxiety, suicidal tendencies may be present, and protective measures may be required. The least amount of drug that is feasible should be available to the patient at any one time.

Patients taking Verstran for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed. Hepatomegaly and cholestasis were observed in chronic toxicity studies in rats and dogs.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

Pediatric Use:
Safety and effectiveness in patients below the age of 18 have not been established.

Adverse Reactions: The side effects most frequently reported during double-blind placebo-controlled trials employing a typical 30 mg divided total daily dose and the percent incidence in the Verstran (prazepam) group were: fatigue (11.6%), dizziness (8.7%), weakness (7.7%), drowsiness (6.8%), lightheadedness (6.8%), and ataxia (6.0%). Less frequently reported were: headache, confusion, tremor, vivid dreams, slurred speech, palpitation, stimulation, dry mouth, diaphoresis, and various gastrointestinal complaints. Other side effects included: pruritus, transient skin rashes, swelling of feet, joint pains, various genitourinary complaints, blurred vision, and syncope. Single nightly dose, controlled trials of variable dosages showed a dose-related incidence of these same side effects. Transient and reversible abnormalities of liver function tests have been reported, as have slight decreases in blood pressure and increases in body weight.

These findings are characteristic of benzodiazepine drugs.

Overdosage: As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

If vomiting has not occurred spontaneously, it should be induced. Immediate gastric lavage is also recommended. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though unlikely, may be controlled with Levophed* (levarterenol bitartrate) or Aramine* (metaraminol bitartrate). Caffeine and Sodium Benzoate Injection, USP, may be used to counteract central nervous system depressant effects.

Dosage and Administration: Verstran (prazepam) is administered orally in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 20 to 60 mg daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a divided daily dose of 10 mg to 15 mg. (See Precautions.)

Prazepam may also be administered as a single dose daily at bedtime. The recommended starting nightly dose is 20 mg. The response of the patient to several days' treatment will permit the physician to adjust the dose upward or, occasionally, downward to maximize antianxiety effect with a minimum of daytime drowsiness. The optimum dosage will usually range from 20 to 40 mg.

Drug Interactions: If Verstran (prazepam) is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monamine oxidase inhibitors or other antidepressants.

If Verstran is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

How Supplied: Verstran (prazepam) 10 mg light blue, scored tablets in bottles of 100 (N 0047-0276-51).

STORE BETWEEN 59°-86° F (15°-30° C).

a valuable link To the resources of the American Psychiatric Association

for institutions and agencies concerned with the care of the mentally disabled

Enrollment in the Hospital & Community Psychiatry Service brings multiple copies of *Hospital & Community Psychiatry* into member agencies every month, keeping staff up to date on developments and issues in the mental health field, offering new ideas and fresh perspectives, and serving as a useful resource in staff development and training programs.

Hospital & Community Psychiatry is just one of the benefits of membership in the H&CP Service. Others include a film library containing more than a hundred films specially chosen for their usefulness in staff development and community education programs; supplementary mailings of important books, reports, articles, or other material of special interest to administrators or clinicians; reduced registration fees at the annual fall Institute on Hospital & Community Psychiatry; and, on request, information and consultation from the professional staff of the American Psychiatric Association. The H&CP Service also sponsors the annual Achievement Awards competition, which gives special recognition to outstanding programs for the mentally ill and mentally retarded.

Please send me information about membership in the Hospital & Community Psychiatry Service.

CLEARING OF DEPRESSION
ANTIDEPRESSANT EFFECTIVENESS... with convenient once-a-day h.s. dosage*
SINEQUAN®
(DOXEPIN HCl)
75-mg CAPSULE
Also available: 100-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE 10 mg/ml, in 120-ml (4-oz) bottles
*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.
See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

IN THE TREATMENT OF CLINICAL DEPRESSION—

SINEQUAN® 75 mg (DOXEPIN HCl) CAPSULE

PROVIDES ANTIDEPRESSANT EFFECTIVENESS

IN ADDITION TO OTHER, OFTEN BENEFICIAL, PROPERTIES...

CONVENIENT ONCE-A-DAY h.s. DOSAGE

which may increase patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and early-morning awakening often associated with depression.

MARKED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have occasionally been reported. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting dose of 25 mg t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.

In more severely ill patients an initial dose of 50 mg t.i.d. may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.

As an alternative regimen, the total daily dosage, up to 150 mg, may be given on a once-a-day schedule without loss of effectiveness. This dose may be given at bedtime.

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg doxepin in bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). SINEQUAN (doxepin HCl) 25 mg and 50 mg are also available in bottles of 5000. SINEQUAN Oral Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 mg doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.

Pfizer **LABORATORIES DIVISION**
PFIZER INC

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty-two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

Basic tool of primitive psychiatry

Fertility protective statues: For pregnant women, the statues insured a healthy, beautiful child, and protected both mother and child from the "evil eye." For sterile women, the statues' magical power aided fertility. Ashanti, Ghana.

From the collection of the Segy Gallery, New York City. Reproduced with permission.

Basic tool of modern psychiatry

Thorazine®

brand of **chlorpromazine**

Tablets: 25 and 50 mg of the HCl

- Effective control of psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 convenient dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings:

Caution is recommended when 'Thorazine' is administered for the treatment of vomiting in children.

Antiemetics are not recommended to treat uncomplicated short-term vomiting in children or vomiting of unknown etiology.

The possibility of extrapyramidal reactions from 'Thorazine' may confuse the diagnosis of Reye's syndrome or other encephalopathy. Although unconfirmed, some suspicion exists that centrally-acting antiemetics may contribute to or adversely affect the course of Reye's syndrome, and should be avoided in suspected cases.

©1967, 1968, 1969 SmithKline Corporation

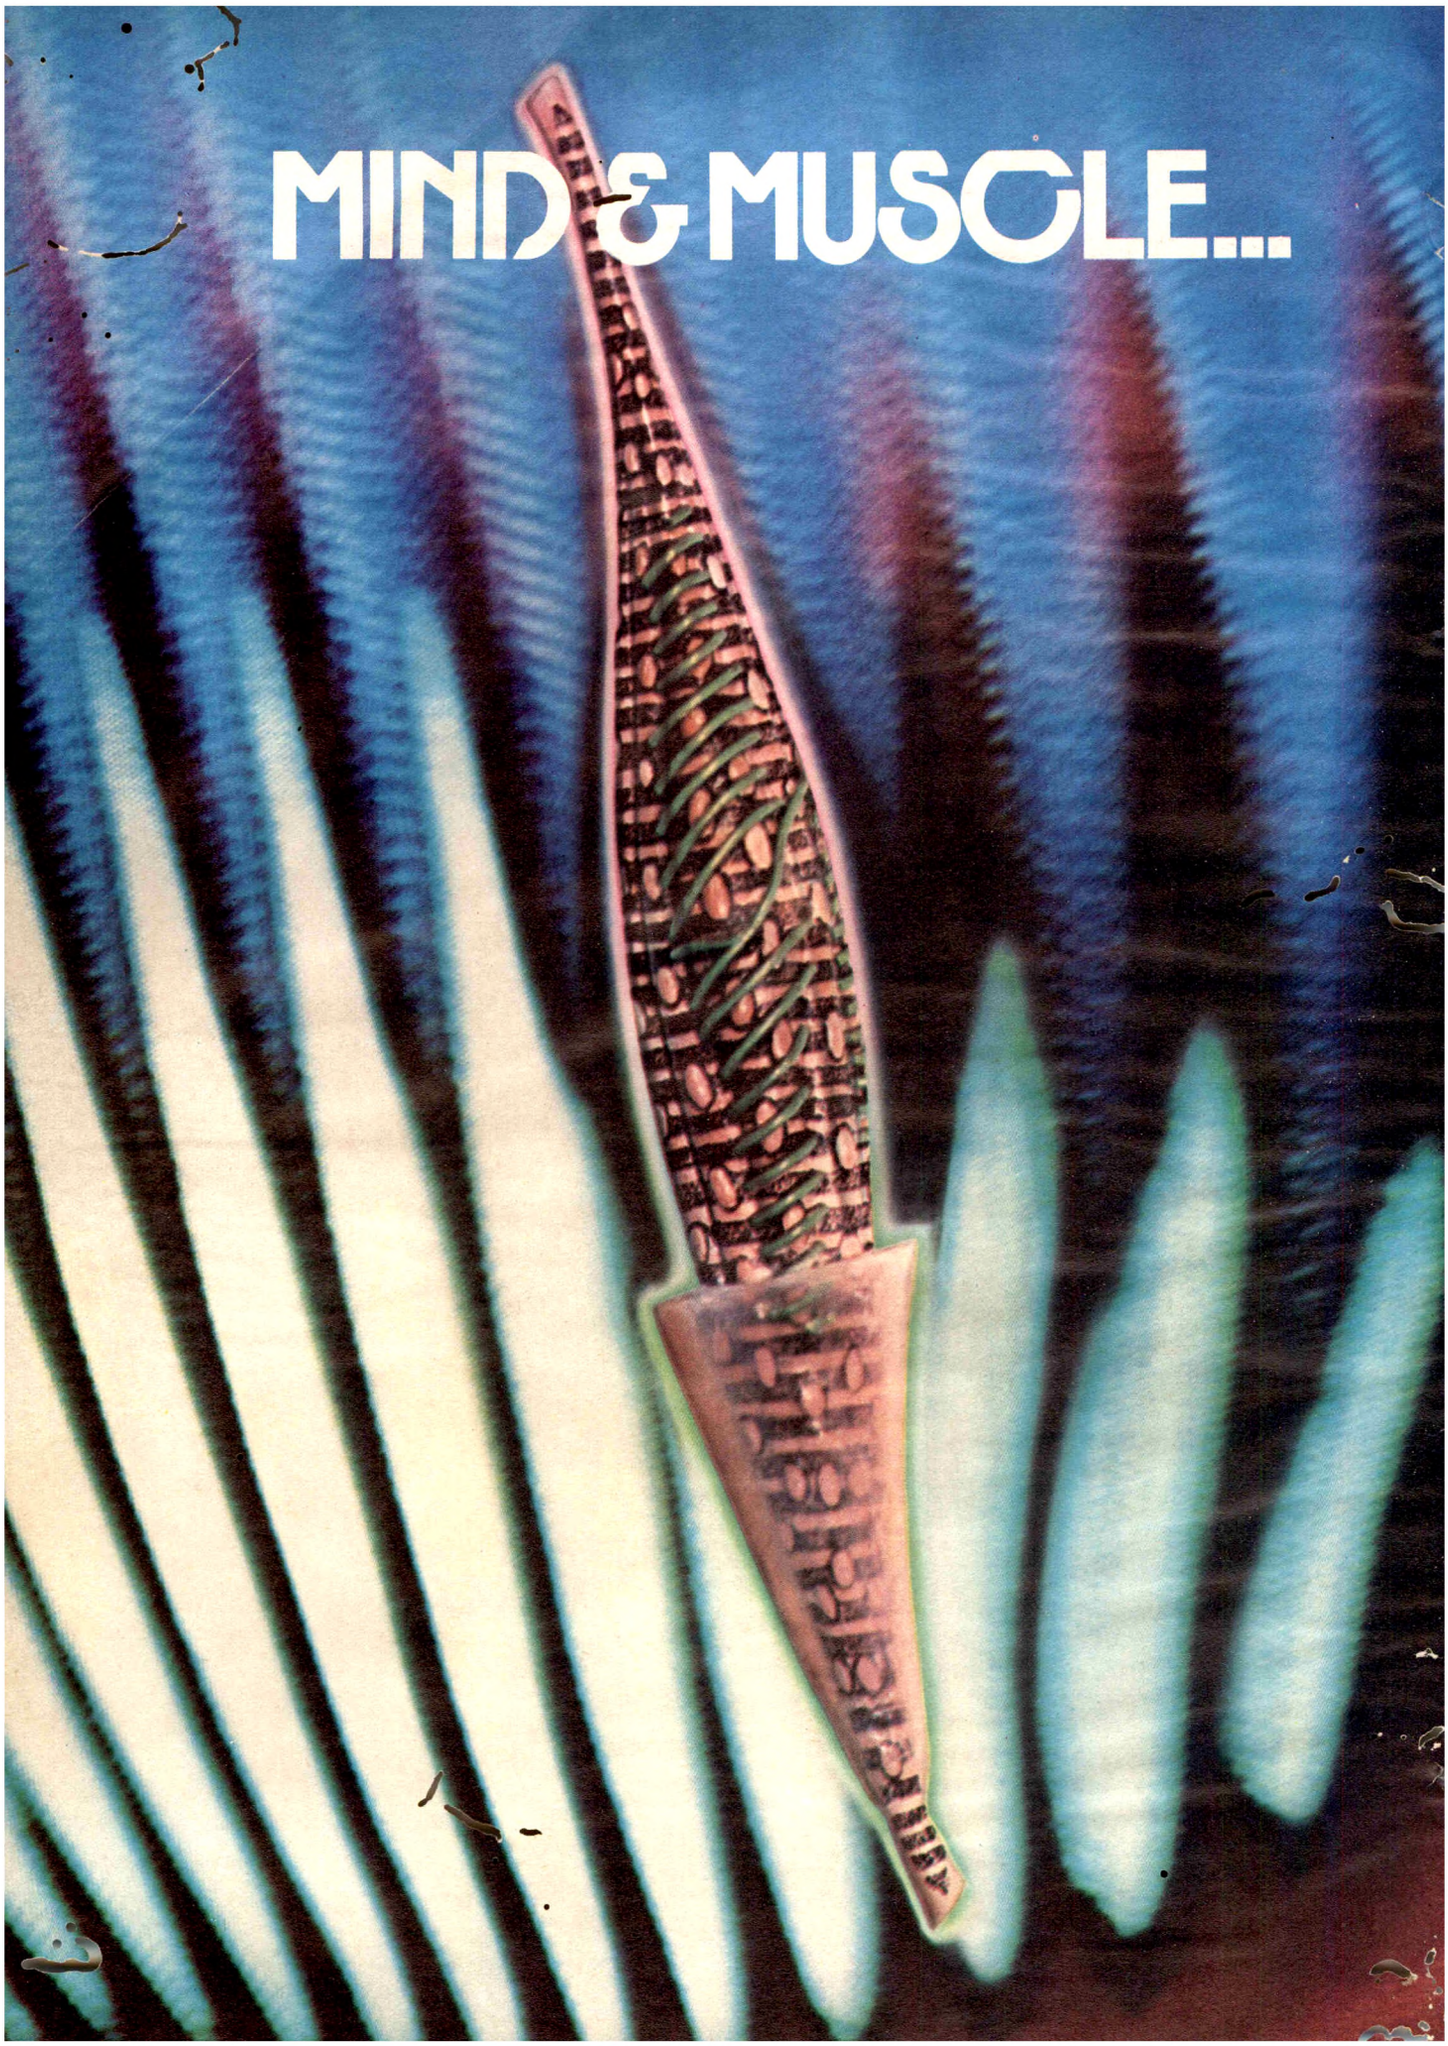
Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.



NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg. Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

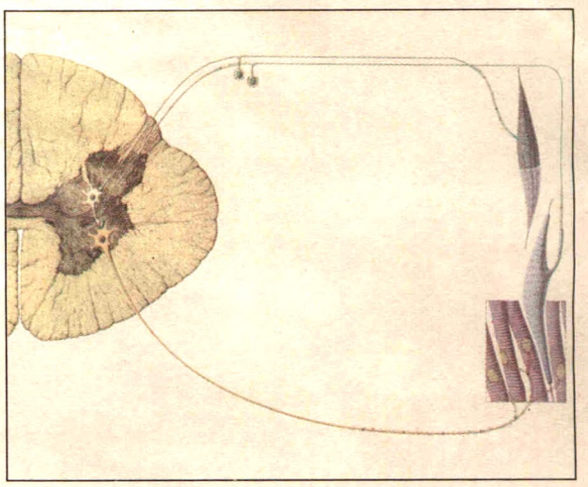
Helps Return Patients to Reality

MIND & MUSCLE...



ONLY VALIUM (diazepam) HAS THESE TWO DISTINCT EFFECTS...

MIND: PSYCHOTHERAPEUTIC

Valium is useful for the relief of undue psychic tension and anxiety whether seen alone or associated with organic or functional disorders, or with secondary depressive symptoms. Valium provides a quality of response you know, want and trust. A response which has a pronounced effect on the somatic symptoms of anxiety.

MUSCLE: SKELETAL MUSCLE RELAXANT

Preliminary studies in both animals and humans have suggested that Valium (diazepam) may also work at the spinal level by enhancing presynaptic inhibition, a mechanism believed to diminish spasm in skeletal muscle. Clinically, adjunctive Valium has significant skeletal muscle relaxant properties.

VALIUM® (diazepam) IV

2-MG, 5-MG, 10-MG SCORED TABLETS

FOR THE RESPONSE YOU KNOW, WANT AND TRUST

Before prescribing, please see following page for a summary of product information.

ROCHE

VALIUM®
(diazepam)

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

COMMISSIONER OF STATE MENTAL HEALTH SERVICES, LITTLE ROCK, ARKANSAS

Primary agency responsibilities include one major psychiatric insititution at Little Rock, a nursing home at Benton and a community mental health program of sixteen Community Mental Health Centers and clinics. Annual Agency budget of $25,000,000 with a workforce of 1,600 employees.

Salary competitive, benefits excellent. Candidates should have completed advanced studies specializing in Mental Health or in Public Administration field with a minimum of five years of demonstrated top level management ability with emphasis in Mental Health.

Professional backgrounds in psychiatry, other medical specialties, and non-medical disciplines such as psychology, public administration, education or social work will be considered. Final selection will be made by a five-member State Mental Health Board and the Director, Department of Human Services. Submit resume in confidence to Mr. David B. Ray, Jr., Director, Department of Human Services, 406 National Old Line Building, Little Rock, Arkansas 72201.

Director of Rehabilitation Services

Brentwood-UCLA Psychiatric Teaching Hospital is seeking Director of Rehabilitation Services, serving 400 inpatient and 2300 outpatients. Psychiatrists, Physiatrists, or other disciplines may apply. Services include Vocational testing, counseling, placement, and training programs, sheltered workshop, occupational therapy, education, recreation, and community projects. Experience in program development and management required, must qualify for UCLA faculty appointment. Involvement in teaching and research encouraged. Salary commensurate with qualifications; plus generous U.S. Government fringe benefits; licensure in any state acceptable; an opportunity for professional growth and personal enrichment in a fine seaside community with clean air and unexcelled academic, cultural and recreational resources. Write Milton Greenblatt, M.D., Chief of Staff, VA Hospital, Brentwood, Wilshire & Sawtelle Blvds. 530/11D, L.A., CA 90073 Phone 478-3711, Ext. 1641, Equal Opportunity Employer

THE AMERICAN JOURNAL OF PSYCHIATRY

NOW, your journals can become an attractive permanent part of your professional library. These famous Jesse Jones volume files, especially designed to keep your copies orderly, readily accessible for future reference—guard against soiling, tearing, wear or misplacement of copies. These durable files will support 150 lbs. Looks and feels like leather and is washable. The 23-carat gold lettering makes it a fit companion for the most costly binding.

Reasonably priced, too. Only $4.25, 3 for $12.00, 6 for $22.00 POSTPAID U. S. A. ORDERS ONLY. Satisfaction unconditionally guaranteed or your money back.

in clinically significant depression...

penetrating the symptom barrier to productive psychotherapy

symptoms often interfere with therapy

In clinically significant depression, the patient often becomes barricaded behind his own symptoms during psychotherapy. Because these symptoms can be so sharply defined and somatic in expression, he may reject the fact that they are psychic in origin. Sleep disturbance, gastrointestinal complaints, anorexia, chronic fatigue, and other psychosomatic symptoms may so preoccupy—or overwhelm—the depressed patient that truly productive therapeutic sessions are difficult to achieve. Instead of being able to concentrate on the core emotional problems of the depression itself, he may for example go on at length about how broken his sleep is or keep reiterating (while the therapeutic hour slips by) how physically miserable he feels.

ELAVIL®
(AMITRIPTYLINE HCl, MSD)
to help penetrate the symptom barrier in depression requiring medication

ELAVIL, a highly effective tricyclic antidepressant, will often alleviate these symptoms. With the help of ELAVIL, sleep disturbance—so common in clinically depressed patients and often the symptom that distresses them most—as

well as other "barrier symptoms" may be lessened to the point where they no longer come between you and the patient.

psychotherapy takes direction

As these preoccupying complaints are lifted, psychotherapy sessions can become more productive. Patients are enabled to respond more fruitfully during therapeutic hours and to resume or pursue more efficiently the necessary activities in their personal lives.

meeting therapeutic goals

And as the antidepressant activity of ELAVIL (Amitriptyline HCl, MSD) takes hold, it helps relieve the depressive condition itself. Sometimes only a minimum of actual psychotherapy is required. The patient may experience a more rapid recovery—while you conserve valuable time.

Prescribe ELAVIL then, to help lighten the patient's burden in depression—and yours in its management.

ELAVIL should not be used during the acute recovery phase following myocardial infarction; in patients hypersensitive to it; in those who have received an MAOI within two weeks; or in children under 12. Patients with cardiovascular disorders should be watched closely. Safe use during pregnancy and lactation has not been established. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Hospitalize as soon as possible any patient suspected of having taken an overdose.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

MSD
MERCK SHARP & DOHME

addendum

To further simplify once-daily therapy for many depressed patients

Tablets

ELAVIL®

(AMITRIPTYLINE HCl | MSD)

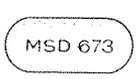
ONE TABLET, ONCE DAILY

—an appropriate way to prescribe for many depressed adult outpatients. Because of its simplicity, this regimen helps improve patient compliance. Of course, ELAVIL may also be prescribed in divided daily doses.

ONCE-DAILY DOSAGE SCHEDULE FOR ADULT OUTPATIENTS:

A single 75-mg tablet
Usual starting dosage

A single 100-mg tablet
Maximum starting dosage



A single 50-mg tablet
Minimum starting dosage

Dosage may be increased by 25 or 50 mg as necessary until a total of 150 mg per day is reached.

A single 150-mg tablet
Maximum daily dosage

ELAVIL MAY ALSO BE PRESCRIBED IN DIVIDED DAILY DOSES

The 25-mg tablet

This strength may prove useful when therapy is initiated with divided daily doses in adult outpatients. Starting dosage is usually 75 mg daily. If necessary, this dosage may be increased gradually to a total of 150 mg a day. Increases are made preferably in the late afternoon or bedtime dose.

The 10-mg tablet

This strength may prove useful for patients who require lower doses, e.g., adolescent and elderly patients. For these patients who can not tolerate higher doses, 10 mg three times a day with 20 mg at bedtime may be satisfactory.

A sedative effect may be apparent before the antidepressant effect of ELAVIL is noted. An adequate therapeutic effect may take as long as 30 days to develop.

NOTE: The usual maintenance dosage of ELAVIL is 50 to 100 mg per day which may be given in a single dose preferably at bedtime. In some patients 40 mg per day is sufficient. This drug is not recommended for patients under 12 years of age.

Contraindications: Known hypersensitivity. Should not be given concomitantly with monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice) *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

Coverage and Utilization of Care for Mental Conditions Under Health Insurance —Various Studies, 1973–74

By Louis S. Reed, Ph.D.
Consultant in Health Economics, American Psychiatric Association

This book reports six studies that add to the growing body of data demonstrating the feasibility of covering mental illness under health insurance. Although in some ways it may be considered a supplement to APA's 1972 book **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (Reed, Myers, and Scheidemandel), all of the data are new. The studies cover the following areas:

- Utilization of mental benefits under the Blue Cross and Blue Shield plan for federal employees, documenting that a "plateau" in the use of these benefits was reached in 1973–74.
- Comparison of benefits for mental and other illnesses under selected employee health benefit plans.
- Coverage of mental illness under collective bargaining agreements of selected unions.
- Utilization of care for mental conditions under the Canadian health insurance program, which gives the same coverage for mental as for other conditions.
- Updating of information on Blue Cross benefits for hospital care of mental illness.
- Data from selected Blue Cross and Blue Shield plans on coverage and utilization of mental conditions, with emphasis on major medical coverage.

80pp. Paperbound

Single copy, $4.00; 10–49 copies; $3.80 each; 50 or more copies, $3.20 each.

SPECIAL OFFER: One copy of this book (regular price, $4.00) and one copy of **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (regular price, $6.50) for $8.50.

Tranxene® CIV

CAPSULES,
SINGLE DOSE TABLETS

(CLORAZEPATE DIPOTASSIUM) 4306CB **Brief Summary**

ACTIONS—Pharmacologically, **TRANXENE** (clorazepate dipotassium) has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine.

INDICATIONS—**TRANXENE** is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of **TRANXENE** for long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS—**TRANXENE** is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS—**TRANXENE** is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on **TRANXENE** should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since **TRANXENE** has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, **TRANXENE** is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:
Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:
An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:
TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS—In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on **TRANXENE** for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS—The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION—
For symptomatic relief of anxiety:
TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For symptomatic relief of acute alcohol withdrawal:
Recommended schedule: 1st 24 hours, 30 mg **TRANXENE** initially, followed by 30 to 60 mg in divided doses; 2nd 24 hours, 45 to 90 mg in divided doses; 3rd 24 hours, 22.5 to 45 mg in divided doses; 4th day 15 to 30 mg in divided doses. Thereafter gradually reduce to 7.5 to 15 mg daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS—If **TRANXENE** is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that **TRANXENE** prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If **TRANXENE** (clorazepate dipotassium) is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE—Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of **TRANXENE** as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed, since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of **TRANXENE** overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to **TRANXENE**.

CLINICAL PHARMACOLOGY—Studies in healthy men have shown that **TRANXENE** has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

Absorption–Excretion:
After oral administration of **TRANXENE**, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-**TRANXENE**, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED—**TRANXENE** (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).
7.5 mg. capsules (gray with maroon cap) in bottles of 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3418-11).
15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 100 (NDC 0074-2699-13).

If you're rethinking your choice of tranquilizers, here are

four good reasons to make it

Tranxene® CLORAZEPATE DIPOTASSIUM

C IV

4306CB

1. Tranxene has been shown equivalent to diazepam in anti-anxiety effectiveness, in controlled studies with hundreds of patients.

2. Tranxene is remarkably well tolerated; excessive sedation is seldom a problem.

3. Tranxene offers oral dosing options unmatched by another tranquilizer: not only conventional divided dose forms, but also economical single-dose tablets for once-a-day use at any convenient hour.

4. Tranxene is physically different in form and appearance from other widely used agents. (Fewer patients will know or recognize it.)
